Mr Laing gives a very minute account of a Norwegian farm rented by a Scotchman; and as he considers it "fitted to be the representative of a large portion of the estates into which this country is divided," we shall abridge his description, retaining all the essential parts. Land in

Norway. Norway is measured by the mæling, which contains forty-nine square ells, the ell containing two feet, and the Norwegian foot being three per cent. longer than ours. Thus the English acre of 43,560 square feet contains four mælings and four tenths. Each farm may be considered as consisting of three divisions. The first is the infield, or what we should call the mains, or home acres, enclosed for the crops and the best hay. The next is the mark or outfield, also enclosed, and affording the out-pasture for the cattle. Parts of it are occasionally fenced off, and broken up for grain, and, when exhausted, are left to sward themselves; so that when the cattle are sent to the Fjelde in summer, some hay is got from the mark. There is often a still rougher piece of ground divided from the mark, as a range for goats and young cattle, called the out-mark. The third division is the seater. This is a pasture or grass farm often at the distance of thirty or forty miles up in the Fjelde, to which the whole of the cattle and dairy-maids are sent for three or four months in summer. The huts on these seaters are substantial buildings, with every accommodation necessary for the dairy; and butter and cheese are accordingly made in very considerable quantities. When speaking of farms of so many mælings, the seater and mark are not included in the measurement, but thrown in as appendages. "The farm of my countryman," says Mr Laing, "consists of 1276 mælings, or 290 English acres; but this does not include the seater, which happens here to be on the hills immediately behind the farm, is covered with fine trees, and is of a defined boundary, extending about a Norwegian mile (seven English miles) in circuit. On the measured land 148 acres are cleared; but, being farmed in the Norwegian style, one third only bears crops of corn and potatoes. The remainder is always in grass or hay, for the winter support of the cattle. It is natural grass, not top-dressed with manure, and is mown when not above the length of one's finger, so that the proportion of arable land that must be given up to keep the cattle in winter is enormous. It is the system of farming in this quarter; 142 acres outside of the 148 infield are half cleared, being fenced off and ploughed in patches. It bears good grass, but is encumbered in some places with brushwood and stones."

"This farm supports twenty cows, seven horses, and a score or two of sheep and goats. The accommodation for cattle is excellent. They stand in a single row in the middle of a wide house, with partitions between each, and room before and behind greater than is occupied by the animal itself. The cow-house is lighted by glass windows on each side. The cattle stand on a wooden floor, below which is a vault, into which the dung is swept by a grated opening at the end of each stall." All the cow-houses in Norway are constructed on this large and convenient scale; and neither cows nor horses require litter, which is a great saving of fodder. Besides, they are kept perfectly clean, with comparatively little trouble. The annual rent of this farm was two hundred dollars, or L.37. 10s. sterling, and the amount of taxes paid was L.6. 14s. 5s., nearly one sixth of the rental, which appears very heavy. But this is nearly all that is paid in any shape; the indirect taxes, such as our excise and custom-house duties, being inconsiderable. It includes tithe, and all charges connected with the church establishment, poor rate, and so forth. Such a property as that now described is considered worth about 4000 dollars. From 2500 to 4500 dollars include, it appears, the prices of all ordinary estates, and any thing very much above or below would be an exception to a general rule. As to the dwelling-houses on such estates, the material for building is so easily obtained that there is really no difference between the residence of a public functionary, of a clergyman, or of a gentleman of large property, and that of a bonde or peasant proprietor. The Norwegians are the best lodged people in Europe, Mr Laing says; but there is little show, and no magnificence which can well be dispensed with in such a country. The division of property among children prevents the erection of splendid mansions, or any thing more expensive than is proportioned to the property upon which they stand. The harvest work in this district," continues our traveller, "and I believe all over Norway, is well done; and parts of their management might be adopted with advantage in our late districts, where so much grain is lost or damaged almost every autumn by wind or rain. For every ten sheaves, a pole of light strong wood, about the thickness of the handle of a garden rake, and about nine feet in length, is fixed in the ground by an iron-shod borer; it costs here almost nothing. A man sets two sheaves on the ground against the stem, and impales all the rest upon the pole, one above the other, with the heads hanging downwards." This is certainly a mode very superior to ours; and they have likewise a better way of cutting it, by which little of the grain is lost. But for an account of this process, and other farming operations, we must refer to Mr Laing's work (pp. 96, 106).

The breed of cattle in Norway is fine boned, thin skinned, and kindly looking; the colour is generally white, sometimes mixed with red, but seldom entirely black. The head and muzzle are as fine as in our Devonshire breed. There is so little coarseness about the head or neck of the bull, that the difference between him and the ox is less observable than in our breeds. The cattle are all very carefully attended to, and form an important branch of the husbandry, as dairy produce enters much into the food of every family, and is more certain in this climate than that of grain. The cows, sheep, and goats are more tame and docile than they are in Britain, from the constant care and attendance bestowed on them during the long period which they must stand within doors; and the Norwegians are remarkably kind to their domestic animals. Goats are a favourite stock, and on every farm appear to be much more numerous than sheep. The goat will eat and thrive on the shoots of the dwarf birch, beech, and young fir; but the sheep will not, and in winter it requires some hay. The goat then gets a bundle of dried leaves and shoots of the beech, which only cost the trouble of collecting and drying them. Every farm-house at this season is surrounded with bundles of these withered branches and leaves of beech tied together, and stuck upon poles to dry. The goat, too, gives some milk in winter, when that of cows is scarce; and from the uncommon richness of milk in Norway, this small quantity can bear to be increased with water, without materially deteriorating it.

Irrigation is carried on in many parts to an extent quite unknown in this country. Hay being the principal winter support of live stock, and both it and corn, as well as potatoes, being liable, from the shallow soil and powerful reflection of sunshine from the rocks, to be burned and withered up, the greatest exertions are made to bring water from the head of each glen, along such a level as will give the command of it to each farmer at the head of his fields. This is done by conducting water in troughs made of the half of a tree roughly scooped out, from the highest perennial stream amongst the hills, through woods, across ravines, along the rocky and often perpendicular sides of the glens; and from this main trough lateral branches shoot off to each farm. The farmer distributes this supply by moveable troughs amongst his fields, watering each rig successively. The quantity of land traversed by these artificial water-courses is very great.

In winter, when agricultural operations are suspended, the Norwegian employs himself in making all the implements, furniture, and clothing, which his family may require; thrashing out the crop, attending to the cattle, distilling his potatoes, brewing, driving about to fairs, or paying visits. The heaviest of his occupations is driving wood out of the forests, or bog-hay from the Fjelde, where it is made in summer by those who attend the cattle. The distillation of spirits from potatoes is general throughout Norway, grain not being in such abundance as to allow of its consumption in this way. By far the greater part of the spirits used in the country is made in families, not in regular distilleries; every common bonde, or peasant proprietor, distilling his own few barrels. It is part of the women's work, like cheese making or brewing, and is carried on once a week or once a fortnight, on every gaard, for the sake of the wash and refuse to the cattle, as well as for the spirits. The most profitable way of distilling potatoes," says Mr Laing, " is with a mixture of crushed wheat and malt, or, instead of wheat, rye or any other kind of grain. The best proportions are these :— To six heaped barrels of potatoes, weighing seventy-eight stones of sixteen pounds each, nine and a half stones of wheat or other corn, and five of malt from bear or big. If more of any of the parts be taken, the wort or liquor to be distilled is too heavy, and is apt to burn or singe in the still. By this proportion the smallest distilling, as a barrel or half a barrel at a time, is regulated. The crushed grain and malt are first mixed in about a hundred and twenty quarts of water, heated to 50° of Reaumur, or 144° of Fahrenheit, and no higher. The potatoes being perfectly steamed (brought to such a state as to be fit for eating), are crushed between two rollers, and, as they leave the rollers, are shovelled into the vat in which the fermentation is to take place." " Boiling water to the extent of about four hundred and fifty quarts is then poured into the vat, and is cooled down with cold water to 20° Reaumur, or 77° Fahrenheit, at which the mash of wheat and malt is added to it; the vat is then immediately covered up as tightly as possible, and left to ferment." After fermentation has ceased, distillation immediately commences, the process being conducted in the usual way. Somewhat more than eighteen quarts English, of a strong fiery spirit, destitute of any disagreeable taste or smell, is produced from the barrel of potatoes. Of its exact strength Mr Laing was unable to form any judgment.

In Norway there is no restriction on mills, every man who chooses having a right to erect one, without entailing upon himself any feudal burden, such as service, suit, or feu, for he is the superior of his own lands. These mills are very numerous in the country, being not only necessary to almost every farm, but for sawing timber for exportation, as well as for home consumption.

The thrashing machines in general use amongst agriculturists are similar in construction to those of Scotland; and some have grinding machinery attached to them. There is an institution of a very peculiar nature, which is quite common all over Norway. In this country there are no merchants equivalent to our corn-dealers, nor are there any weekly markets held for the sale of grain. There are no middle-men between the grower and the consumer, and any surplus grain which the farmer may have is stored up in what may be called corn-magazines, which are just large warehouses erected in various parts of the country, as the necessities of the inhabitants require them. What grain the farmer thinks he will not require he conveys in sledges to these places, and for every eight bushels which he deposits, he receives nine at the end of twelve months; in short, he lays it out at interest, and has an increase of one eighth per annum. If, however, he has none deposited, or overdraws, he pays for the quantity received in loan at the rate of one fourth of increase per annum; so that for every eight bushels which he takes he pays back ten at the end of twelve months, or at that rate for whatever time he may have the loan This is, in fact, a savings' bank for corn, and is probably the most ancient of these institutions. There being no corn-merchants is decidedly a material check upon the prosperity of agriculture; for, from the want of a ready market where he might dispose of his produce, and the consequent comparatively small inducement which he has to store it up in these magazines, the farmer naturally wastes it, or does what is probably worse, distils it into ardent spirits. But these institutions are exceedingly useful to the Norwegians as they are circumstanced; and were it not for them, many might be placed in great difficulties, for want of seed or bread when a bad season disappointed their hopes of a supply from their own fields. The small profit which occurs upon these transactions defrays the necessary expenses of building and keeping up the magazines, which are entirely under the management of the bonder or peasant proprietors. However, under such a system, husbandry can never become what it is in Great Britain, a manufacture of corn, beef, and other provisions, carried on by a class of individuals who pay a very high rent for the premises on which they work, and embark large capitals in the business. In Norway the bulk of the farmers have no rent to pay, the property being their own; the articles which their farms produce constitute nearly the whole of the food or raiment which they and their people require; and there are not, as in other countries, considerable masses of population in towns and villages, who, not being producers of food themselves, must obtain it from those who are; so that the farmer is less dependent upon money-bringing crops than is the case with us. If he raise what is sufficient for his own household consumption, with a little surplus for sale to pay the taxes, and for the purchase of a few luxuries, all the purposes of farming are served with him. This is partly owing to the state of property in Norway.

State of property.

Property in Norway is held by what is called the udal or odel system of rights, not from any superior, not even from the king, but, as the possessors proudly express it, by the same right by which the crown itself is held; consequently there is no acknowledgment, real or nominal, as feu-duty or reddendo, paid. In this country all lands are theoretically said to be held from the king; and, according to Sir Edward Coke, we have no allodial lands. In Norway estates are allodial, the absolute property of the owner; they are therefore possessed without charter, and are subject to none of the burdens and casualties affecting land held by feudal tenure direct from the sovereign, or from his superior vassal. There is, in short, a total negation of the feudal principle; there is neither superior nor vassal, so that the military service which the latter paid to the former in consideration of the land which was granted appears never to have existed in Norway; and as this constituted the foundation of the law of primogeniture, so, where such service was entirely unknown, there was no necessity for that law, which consequently remained equally unknown. In all feudal countries the eldest male heir has to pay an acknowledgment to the feudal superior on his entering as vassal in the land. But udal, or noble land, as the word signifies, not being held for military service to a superior, no *delectus personæ* as to who should inherit it was competent to any authority, and consequently no preference of the eldest male heir could grow into the law of succession to land. Hence the land came to be equally divided amongst all the surviving children, male and female. There appears, however, to be a species of entail connected with the udal tenure. If the udalman in possession should alienate to a stranger, the next of kin has a right of redemption on paying the price of the land. This is called the Odelbaarn's Ret, and all the kindred of the udalman in possession

Norway.

are what is called Odelsbaarn to his land, or, in other words, have a certain right in the order of consanguinity. By recent enactments, this right of redemption has been limited in its exercise to a period of five years; and it is provided that all improvements, as well as the original price, must be paid for.

The equal partition of property amongst children by the udal tenure has prevented the accumulation of property in large masses; but, as might have been expected by theorists, it has not led to subdivisions of estates to an injurious extent. "The division of the land appears not," says Mr Laing, "during the thousand years it has been in operation, to have had the effect of reducing the landed properties to the minimum size that will barely support human existence. I have counted from five and twenty to forty cows upon farms, and that in a country in which the farmer must, for at least seven months in the year, have winter-houses and provender provided for all the cattle. It is evident that some cause or other, operating on aggregation of landed property, counteracts the dividing effects of partition among children." In another place Mr Laing says, "The estates of individuals are generally small; and the houses, furniture, food, comfort, ways and means of living, among all classes, appear to me to approach more nearly to an equality to one standard than in any country in Europe. This standard is far removed from any want or discomfort on one hand, or any luxury or display on the other. The actual partition of the land itself seems, in practice, not to go below such a portion of land as will support a family comfortably, according to the habits and notions of the country; and it is indeed evident that a piece of ground without houses upon it, and too small to keep a family according to the national estimation of what is requisite, would be of no value as a separate property. The heirs accordingly either sell to each other, or sell the whole to a stranger, and divide the proceeds. The duty of the Sorenskriver, or district judge, consists chiefly in arranging this kind of chancery business, and all debts and deeds affecting property are registered with him."

The cause which, according to Mr Laing, has prevented excessive subdivision, is, "that in a country where land is held, not in tenantry merely, as in Ireland, but in full ownership, its aggregation by the deaths of co-heirs and by the marriages of female heirs among the body of landowners, will balance its subdivision by the equal succession of children." This is undoubtedly true, and, when taken in connection with other facts, may sufficiently explain the case. Mr Laing informs us that the standard of living is high in Norway; or that the population is much better clothed, lodged, fed, and generally provided for, than our labouring and middling classes in the south of Scotland. The dwelling-houses of the meanest labourers are divided into several apartments, and have wooden floors and a sufficient number of good windows, with some kind of out-house for cattle and lumber. Their food and clothing are equally good and substantial. Now it seems quite clear that a people habituated to such a standard of subsistence and comfort will not only not suffer their condition to sink indefinitely below it, but, by prudence and foresight in the contraction of marriage and the raising of a family, will keep down their numbers considerably within their means of subsistence. In Norway that condition which secures respectability to a common man, is one in which he commands not only all the comforts, but most of the luxuries of life, common to the country; and the natural desire of all mankind to keep up caste, to maintain themselves in that station in which they were born, not to decline from it, and fall, as it were, out of the ranks, will operate as a most powerful check upon the minute subdivision of land. There are other causes in operation to which our circumscribed limits will only admit of our adverting. These are the ancient and confirmed habits of the people, which may be taken into account as a corollary of the preceding proposition; and the absence of impediments, such as fines on alienation, or imposts of any kind, in the way of sale or conveyance. Where such fines exist, the difficulties of re-uniting land which has been subdivided are great and annoying. But in Norway, when an udalman dies, the co-heirs do not break up the estate left to them into six or eight, or any other number of estates, corresponding to the number of children; which would at once reduce the standard of living of the whole of them below that to which they were accustomed. They appear either to sell to each other, which is easily effected in the absence of fines and other burdens on conveyance of property; or they make a joint-stock business of it, till circumstances permit some of the members to dispose of their shares to those who may remain, and employ the capital in such an advantageous manner as will secure them in that comparative independence and affluence to which they were all their lives accustomed. The diffusion of property in Norway is no doubt very great, compared with its diffusion in this country, but not as compared with Canada. The following table will facilitate comparison:

Country.	Population.	Proprietors.	Proportion of Proprietors to Population.
Scotland........	2,093,456	8,961	1 to 222
Norway..........	910,000	41,656	1 to 22
Lower Canada..	512,000	57,891	1 to 9

These small estates are scattered on the sides of glens, lakes, and fiords, over a vast extent of country, and, generally speaking, are situated at great distances from towns.

There are two classes of landholders in Norway; those who have farms larger than they themselves can cultivate, and those who exclusively farm their own estates. These constitute the bulk of the population. The first are called proprietors, a sort of conventional term, equivalent to our esquire; the smaller landholders who work upon their own estates are called *bonder*, a term, as appears, nearly equivalent to feuar in Scotland. The incomes of the former seldom exceed eight hundred or nine hundred dollars, although there are some who possess as much as three or four thousand pounds sterling per annum. The Norwegian valleys are crowded with bonder farms, which are very numerous throughout the country, and, with their look of plenty and completeness, may compete with the richest and most beautiful in Scotland. Mr Laing draws a very pleasing and interesting picture of this class of people, whose comfort and happiness may indeed be inferred from a short statement of facts. They are owners of their own little estates, which produce all the necessaries of life, and afford a surplus for the payment of taxes and the purchase of luxuries. They have no feu-duty nor other incumbrance on their property, except the scot or land-tax, which, although heavy, renders every thing used by a family so much cheaper, the indirect taxes being little or nothing. They are exceedingly well lodged, and the families live abundantly; the manner of living, indeed, is pretty much the same amongst all classes. These, and the comfortable assurance, that in case of death the udalman leaves his wife and family provided for, are certainly calculated materially to promote human happiness. "This class," says Mr Laing, "are the kernel of the nation. They are in general fine athletic men, as their properties are not so large as to exempt them from work; but large enough to afford them and their households abundance, and even a superfluity, of the best food.", Besides the bonder or agricultural class, properly so called, who occupy all the most fertile lands in the country "from the shore-side to the hill foot," whereon corn will grow, there is another class called Fjelde bonder, who form a connecting link, as it were, between the class above described and the wandering Laplander. They also possess land, and have houses, which, although small, are comfortable; but being above the level of the corn growing country, their situation is not so favourable, nor is their condition equal to that of the other small proprietors. The Fjelde bonder are "the hewers of wood and drawers of water" in Norway; but they still possess property in cattle as well as in land, and they are described as extremely hardy and active, and as having more robust frames than the agricultural bonder. There is yet another class of the population, which is altogether distinct from any of the preceding, consisting entirely of fishermen, whose social condition must be considerably inferior to that of the others.

In the provinces of Nordland and Finmark, which occupy the northern part of Norway, beyond the river Namsen, agriculture is but a secondary business, and fishing may be said to occupy most of the attention of the inhabitants. The crops of grain are too inconsiderable and precarious to afford them the means of subsistence, and the riches of the deep are brought in as a compensation for the poverty of the land. The winter fishery in the Lofoden Islands, from the middle of February to the middle of April, and the summer fishery over all the coast, which in some branch or other gives employment for the remainder of the year, furnish the inhabitants with the means of purchasing the necessaries which they require. The fish trade is a very curious monopoly. It does not belong to Norway as a whole, but is in the possession of Bergen, Drontheim, Christiansand, and one or two other towns of minor note. Those who manage the business as merchants or shop-keepers, are licensed burgesses of these towns; and each has a certain tract of coast or circle belonging to his shop or factory, within which no other person is entitled to buy or sell. These privileged traders pay a certain tax, and are besides obliged to receive and entertain travellers; and their exclusive privilege has become hereditary, attached to the house or factory in which it may be exercised by a duly privileged trader. The average value of the winter fishery has been estimated at L.86,500 sterling; and as the number of inhabitants in the two provinces is only about 80,000, the trade of Nordland and Finmark with the rest of Norway is at the rate of little more than twenty shillings a head. The merchants send out vessels furnished with articles required in the country, and receive the produce of their eight weeks' fishery in payment. In fact, these distant provinces are connected with the rest of the country for just two months in the year, and that only through a few merchants in two or three towns. During the other ten months the trade is left entirely in the hands of the Russians, who feed the population, and receive in return all that their industry produces in the fishing. The privileged Norwegians take no more brandy, colonial produce, or such other articles as are wanted, than what is sufficient to pay the persons who fish for them for eight weeks; their further supplies the inhabitants obtain from Russia. Were the trade free to all the natives of Norway, as it is in every country where trade has flourished, there would have been a body of Norwegian traders to and from these provinces, carrying on every branch in which employment and profit could be found and realized. Instead of this, the business is almost entirely in the hands of strangers, and Norway receives little or no benefit from her own possessions. To the absurdity of such a monopoly it would be difficult to find a parallel in the history of commercial restrictions.

The fishing business itself is conducted in a peculiar manner. Every twenty or thirty of the fishing companies have a yacht, or large tender, which conveys the provisions, nets, lines, and other articles, to the Lofoden Islands, the great scene of the Norwegian fishery, and brings back the produce. The stations are all correctly defined by marks on the coast, and by judicious regulations confining line-fishers to the inside, and net-fishers to the outside. In 1827, which was a medium year, there were 2916 boats fishing in eighty-three different stations, accompanied by 124 yachts or tenders, the number of men employed being 15,324 in all. The produce was 16,456,620 fish, which would amount to about 8800 tons dried; there were also 21,530 barrels of cod oil, and 6000 of cod roe. When this fishing ends, the seafaring peasantry of this part of the country, as we have already said, are employed by the Russians; the others return to their homes, and catch sethe (*gadus virens*) or herrings. The herring fishery is very judiciously managed; so much so, indeed, that the Norwegians have beaten the Scotch herring curers out of the markets of the Baltic, as they deliver fish better assorted, and of superior quality. Besides these important general fisheries, there is in every creek of the fiords, even at a hundred miles up from the ocean, abundance of cod, whitings, haddocks, flounders, sea-bream, and herrings, caught for daily use and for sale by the seafaring peasantry. The rivers and lakes are likewise well supplied with fish, which may indeed be said to constitute the basis of a Norwegian repast.

Trade and manufactures.

The manufactures of Norway are too unimportant to detain us long. Wood and fish are the chief produce of the country; and these find their way to every part of Europe, chiefly in Norwegian vessels, which in return bring home whatever foreign articles are required, at the cheapest possible rate of freight. The import duties are very moderate. Articles which have been in use, and are not intended for sale, as furniture, books, clothes, or household goods, are not subject to duty. Before the importer pays his duties, he is allowed to take his goods to his own warehouse and shop, upon giving security for the amount of the duties ascertained by the custom-house officers at landing; he also keeps an account of his sales, and pays the duty every three months upon the quantity which appears to have been sold. This must be of great advantage to the dealer in a country so poor as Norway, since it leaves his capital entirely free for active employment. Coffee, sugar, tea, a little French brandy, and French and Spanish wines, a little tobacco, (for the Norwegians smoke less than any other continental people), and a limited quantity of spiceries, are the principal articles for which the house-keeper has to disburse money. The other necessaries of life are produced by themselves. Shoes, furniture, cloths, and the like, are all made at home. Looms are at work in every house in the country; carding, spinning, and weaving forming constant occupations of the female part of the household. Woollen cloth, substantial but coarse, excellent bed and table linen, and checked or striped cotton or linen for female apparel, are the ordinary fabrics produced. These home-made stuffs, including boots, gloves, and in bad weather great-coats, clothe the greater part of the inhabitants, and more comfortably than is the case with the lower and middling classes of people in most other countries. The upper ranks, or the people of condition, dress as in other parts of Europe; and as living and lodging are nearly on a level amongst all the respectable classes, the peasant proprietor, and those more wealthy than he is, this wearing of foreign articles by the latter, and home-made stuffs by the former, would seem to constitute a kind of conventional distinction between them. This is not the place to speculate on the general economy of these family manufactures; it seems, however, to be extremely well adapted to the Norwegians,

Norway.

as they are circumstanced, both in regard to climate and social relationship.

The principal articles of export are timber, bark, iron, copper, fish, and some others. The principal articles of import are corn, colonial produce, woollen, linen, and cotton goods, wine, brandy, &c. Salted and pickled fish, one of the staple products of Norway, is principally exported from Bergen. In the year 1833, there were exported from this place, of dried fish or stock fish, 22,620,992 pounds, and of salted and dried fish 4,802,000 pounds. The deals of Christiania have always been held in the highest estimation; a consequence of the excellence of the timber, and of the care with which the sap-wood and other defective parts are cut away. Like many other branches of the trade of Norway, that of preparing wood was formerly fettered by pernicious restrictions; the saw-mills being licensed to cut a certain quantity only, and the proprietors bound to make oath that it was not exceeded. But this absurd regulation no longer exists. British manufactured goods are admitted into Norway on moderate duties, and are very generally made use of. The imports from Norway were,

	In 1831.	In 1835.
Bark for tanning and dyeing...	48,131 cwts.........	20,043 cwts.
Iron	377 tons.........	4 tons.
Goat-skins..........................	18,219 number	7,837 number.
Smalts	206,840 lbs...........	90,563 lbs.
Battens and batten ends........	8,439 grt. hund ..	5,415 grt. hund.
Deal and deal ends..............	10,457 do. do.....	4,704 do. do.
Masts, yards, and the like,.... under twelve inches.........	4,826 do. do.....	6,842 do. do.
Timber................................	23,527 loads........	30,446 loads.

These are the principal articles; but there were some others, amongst which may be reckoned one million of lobsters. The exports to Norway were,

	In 1831.	In 1835.
Coffee	535,491 lbs............	310,459 lbs.
Indigo	7,765 lbs................	8,631 lbs.
Pepper	8,189 lbs................	1,920 lbs.
Pimento....................	4,981 lbs................	4,348 lbs.
Rum....	4,585 galls..............	6,248 galls.
Muscovado sugar........	3,169 cwts...............	1,298 cwts.
Tobacco................	366,024 lbs............	475,338 lbs.
Cotton wool............	83,566 lbs	39,227 lbs.
Coal........................	3,774 tons	5,602 tons.
Cotton cloth...........	434,744 yards..........	691,320 yards.
Earthenware..........	L.3,402	L4,502
Cutlery.................	L.2,648	L.3,646
Soap and candles......	L.2,938	L.3,302
Woollens..............	L.13,000	L.17,229
Salt.......................	92,150 bushels.......	147,057 bush.
Wheat	....	1,283 qrs.
Barley.......................	....	24,471 qrs.

In some articles our trade with Norway has declined, but the amount of British and Irish produce and manufacture exported to that country has steadily increased, as the following statement will show. Our exports were, in 1827, L.39,129; in 1828, L.53,582; in 1829, L.64,234; in 1830, L.63,926; in 1831, L.58,580; in 1832, L.34,528; in 1833, L.55,038; in 1834, L.61,998; and in 1835, L.79,278.

Were the discriminating duty on Norwegian and Baltic timber repealed, our commercial relations with the whole north of Europe would be greatly extended. Compared with the Swedish customs-duties, those of Norway are moderate, the import duties seldom exceeding two per cent. *ad valorem.* In 1831 they amounted to L.161,840 inwards, and to L.47,381 outwards, making in all L.209,221. To these should be added L.27,436 received on account of tonnage duties, lights, and sundries. The weights and measures of Norway are the same as those of Denmark.

With regard to money, the principal silver coin in circulation (for there are none of gold) is called a species dollar, which is divided into one hundred and twenty skillings. There are also half species, one fifth species, one fifteenth species, and what is denominated skillemynt or small change, that is, four and two skilling pieces of silver, and also one and two skilling pieces of copper. The dollar is worth three shillings and tenpence sterling at the present rate of exchange (1837). There are, besides, notes of one dollar, half a dollar, and twenty-four skillings, all printed on white paper. The notes of five dollars value are on blue paper, those of ten dollars on yellow paper, and those of fifty on green paper. This is, we think, a very wise and convenient arrangement.

The Norwegian finances are in a flourishing condition, the revenue having latterly increased considerably. The Bank of Norway, which was founded in 1816, has its head office in Drontheim, with branches in the principal towns, and is under the direction of five stockholders, with a council of fifteen representatives of the other proprietors. The transactions of this bank are conducted upon a principle totally opposite to that of the Scotch and other banking establishments. It is there considered as a first principle that the bank should hold only available securities, as bills or bonds at a short date, or payable at a short notice, for its issues or advances. The national bank of Norway is therefore a bank for landed property, and discounts mercantile bills and personal securities only as a secondary branch. Its chief business is advancing its own notes, upon first securities over land, any sum not exceeding two thirds of the value of the property, according to a general valuation made in the year 1812. The borrower pays four per cent. for what he draws, and is bound to pay also five per cent. of the principal yearly. This kind of bank is exceedingly well adapted for the wants of the country; and their paper can scarcely be considered as less secure than their silver. Since it commenced business, discussions have more than once taken place regarding the return of the bank to cash payments, as it was originally agreed that after the lapse of a certain period it should begin to pay its notes in cash. This has not been found practicable, although the maximum has been reduced to 125 paper dollars for 100 of silver; but the paper dollar has for a considerable time been at 112 for 100 silver on the exchange of Hamburg. The bank is able to provide for all its notes in silver; and the question recently agitated in the Storthing was, whether its course of 125 paper for 100 silver dollars should not now be reduced to par, 100 paper for 100 silver, which has not been agreed upon.

The Norwegian army consists of some twelve thousand troops of all arms, besides which there are thirty thousand militia enrolled. Two companies belonging to each regiment in the Norwegian service are trained to the use of the skidor or skate. This corps, called the skielöbere, move with singular agility and speed, and, whilst skating along with the greatest velocity, perform their military evolutions with uncommon precision. The army is at the disposal of the king, as far as its services can be rendered available in Scandinavia; it cannot, however, be sent beyond the limits of the peninsula without the special permission of the Storthing. The king has the nomination of the superior officers of the army, as well as of some few of the first civil officers under the government; that of others rests with the Storthing. Norway is governed by a viceroy, appointed by the king of Sweden; Christiania, the capital of the country, being the seat of government. She contributes nothing towards the expense of the Swedish government beyond a trifling annual allowance to the royal family; but she supports all her own civil and military institutions.

In the year 1825 the population of Norway amounted to 967,959. According to the census of 1835, it was 1,098,291, being an increase of 130,332 in ten years. The town population of 1825 was 112,778, and in 1835, 125,139, being an increase of 12,361 in the same period; and that of the country amounted in 1825 to 855,181, and in 1835 to 973,152, being an increase in ten years of 117,971. It is quite clear, therefore, that the great bulk of the population is engaged in agricultural pursuits; trade, manufactures, and the other occupations employing but a very limited number. The town population is confined to thirty-eight places, only nine of which have more than 3000 inhabitants, and only two reach 20,000. Besides, in the whole of these, with the single exception of Bergen, a considerable proportion of the inhabitants are partially engaged in agriculture. During these ten years, no manufacture has been produced fit to be exchanged for the commodities of other countries. The staple trade in wood, which formerly gave employment to a large portion of the inhabitants, has latterly been in a very depressed state, from the restrictive duty already referred to. The increase of population, therefore, has chiefly taken place amongst the agricultural classes; and the additional food raised for their support, together with the admitted advance of the people during these ten years, is to be attributed partly to additional tracts of land having been taken in, and partly to improved methods of cultivating the old soil. The country has unquestionably made great progress under its own peculiar legislation; and taxes have gradually been reduced.

The kingdom of Norway is divided into four sees or stifts, each of which is divided into a certain number of districts, corresponding to its size and importance, and these again into parishes, of which there are 336 in the country. The dioceses are Aggershuus, containing Christiania, the capital; Christiansand, the largest town in which bears the same name; Bergen, containing the large and important city of the same name; and Drontheim, which contains the city of Drontheim, situated on the south shore of a great fiord of the same name; the northern territories of Nordland and Finmark, which goes also by the name of Drontheim, being presumed to be in the same see. The stifts are thus distributed. Christiansand occupies the southern extremity of the country; Bergen and Aggershuus occupy, the former the western, and the latter the eastern side of Norway, where it is widest, extending over its whole breadth in that quarter, and being separated by the great mountain chain; still farther north lies Drontheim, which is succeeded by Nordland and Finmark, the most northerly region of Norway, and of which the reader will find some account in the article LAPLAND. Each district, called a fogderie or bailiwick, is under a foged, who has charge of the collection of taxes, police, and all executive functions in his district. Besides this public functionary, there are military officers, who have official residences in the district; and the amtman, and sorenskriver or judge ordinary. Christiania, Bergen, Drontheim, and the other large towns in Norway, will be found described each under its own respective head in this work.

The Norwegians enjoy more political liberty than any other European nation. The parliament, called the Storthing, is chosen by the owners or life-renters of the land who have attained the age of twenty-five years complete. The minimum value which gives a vote is a hundred and fifty dollars, or L.30, a value which, from the large diffusion of property, renders the suffrage nearly universal. To render the elector himself eligible as a representative, it is only necessary that he should be thirty years of age, have resided ten years in Norway, and be altogether unconnected with the state. The voters choose electing men, one to every fifty voters in towns, and one to every hundred voters in counties. The elective franchise is not connected with the place, but with the number of electors; and expands or contracts as they increase or diminish. If numbers change, the power of choosing electing men changes also; and as the Storthing bears a proportion to the number of electing men, the number composing the Storthing likewise varies; but the variation cannot be great, indeed seldom more than two or three. By this self-acting system of parliamentary reform, places which increase obtain a direct voice in the making of laws, whilst such as decrease below fifty electors must join another district. The electing men, on a day fixed by law, choose their representatives, and the body thus elected forms the Storthing. The proportions of members chosen is founded on the principle, that the towns in Norway should as nearly as possible return one third, and the country two thirds, of the whole body, which must not consist of less than seventy-five, nor of more than one hundred members. Each district elects as many substitutes as it elects representatives, to provide against death and other casualties. The Storthing is chosen every three years, and is assembled only once in three years, when it sits for three months, or until the business be despatched. The 1st of February is the day of meeting fixed by law. An extraordinary Storthing may be convened by the king, but its acts must be confirmed by the next regular Storthing. After some preliminary business, such as electing a president, speaker, and secretary, the Storthing divides itself into two chambers. One fourth of its whole number is formed into a second chamber, called a Lagthing, or division, in which the deliberative functions of the legislative body are vested. This chamber appears to be equivalent to a house of peers, but its powers are much more confined. No bill can be introduced there; it must come from the other house, which is called the Odelsthing, or house of commons. The Lagthing can only deliberate upon what is sent to it, and approve, reject, or send back the bill with proposed amendments. It is also the court before which, aided by the Hoieste Ret Court, an independent branch of the state, the lower house may impeach ministers of state. As the Storthing of 1836 consisted of ninety-six individuals, the Lagthing comprised twenty-four members, and the Odelsthing seventy-two. Mr Laing thus speaks of the Norwegian parliament. "The Storthing consists, in fact, of three houses, the Lagthing of twenty-four members, the Odelsthing of seventy-two, and the entire Storthing consisting of the whole ninety-six united in one house. In this latter all motions are made and discussed; and, if entertained, are referred to committees to report upon to the Storthing. The report, when received back from a committee, is debated and voted upon; and if approved, a bill in terms of the report is ordered to be brought into the Odelsthing. This house entertains or rejects the proposed bill, frames and discusses the enactments if it is not rejected *in toto*, and sends it up to the Lagthing or upper house, to be deliberated upon, approved, rejected, or amended." In regard to the passage of bills through these two houses, the practice of the Norwegian parliament does not differ materially from that of our own, except in the more limited functions of the Lagthing, the king having only a suspensive veto. But if a bill pass through three successive Storthings, it becomes the law of the land without the royal assent. This was exemplified in the case of the bill, already mentioned, for the abolition of hereditary nobility. The duties of the Storthing need not be minutely specified; they may easily be inferred. The members are paid for their services; and no executive officer of government can sit in either house.

For legal purposes, the whole country is divided into four stifts or provinces; and these are farther subdivided into sixty-four judicial districts, each of which last compre-

Norway.

Jurisprudence.

Norway. hends several prestigilds or parishes. To each of these divisions there is a distinct tribunal, with a supreme court of ultimate appeal for the whole kingdom, established at Christiania. The lowest court, which is strictly one of equity, not of law, is the court of mutual reconcilement or agreement held in every parish, and over which presides a commissioner, who is elected every three years by the householders, and holds his court once a month, receiving a small fee. Every case or law-suit whatsoever must pass through this preliminary court, where no lawyer or attorney is permitted to practise. Each party states his own case; and if by the judgment or advice of the commissioner the parties are brought to agree, his opinion is duly registered in another court held in the parish, and it has all the validity of a final decision. If, however, the litigants are not satisfied, they carry their case to the lowest legal court, that of the sorenskriver, or sworn writer, which is held in every parish of every district once in every quarter. The sorenskriver's court is of great importance. Besides judging civil and criminal matters, it is the court of registration affecting property in the district, and also for ascertaining the value of and succession to the property of deceased persons. The court next above is the stift-amt court, or that of the province, and is thus constituted. It consists of three judges with assessors, is stationary in the chief town of each province, and is the court of appeal from all the lower tribunals of the province, having at the same time the revision of their administration. It must likewise sanction their decision in criminal matters before sentence can be pronounced. There is, lastly, the Hoieste Ret Court of final appeal. It consists of seven judges, and, by the ground law, is one of the three estates of the constitution, being independent of the executive and legislative branches. To this court appeals are carried in the last resort, from the stift-amt courts, in criminal as well as civil cases.

The Norwegian system of jurisprudence presents some remarkable features, not the least important of which is that the judge is responsible for his legal decision; and in a case of appeal to a higher court, he must there defend his judgment, being liable in damages for a wrong decision. This principle involves a high responsibility, and must occasion some individual annoyance, as well as expense; but it does not prevent able lawyers from becoming candidates for judicial functions; and beyond all doubt it is of great advantage to the public in giving certainty to the law, and in preventing as well as remedying erroneous decisions. The punishment of death was abolished by the Danish government about the latter end of the last century, a measure of questionable expediency in this country, at least where the secondary punishments are by no means perfect. But the punishment which is found the most effective, and which forms one of the most distinguishing characteristics of the country, is that of the "loss of honour." From the earliest times this has been a specific punishment in the criminal law of Norway, standing next in degree to the loss of life. "The possession of property," says Mr Laing, "naturally diffuses through all classes the self-respect, regard for character and public opinion, circumspection of conduct, and consideration for others, which flow from and are connected with the possession of property, and render these influential on the morals, manners, and mode of thinking of the whole body of the people." There is and has always been much more of the real business of the country in the hands of the people of Norway, and transacted by themselves, than is possessed by the inhabitants of any other European nation. Now, as the "loss of honour" involves exclusion from all the functions which naturally devolve upon them, the punishment is very severely felt, and looked upon, even by the humblest peasant, with the greatest dread. Imprisonment is regarded by the great bulk of the population as light compared with the sentence of dishonour; and the prevalence of such a high tone of feeling regarding a check to crime, which in other countries is altogether ineffectual, is a phenomenon in social polity highly to the credit of the Norwegians.

Church. The Norwegian church is in principle and doctrine Lutheran, and remains as it was originally moulded after the subversion of the ancient faith, unaltered by the spirit of innovation, and unviolated by the hand of power. It is essentially ceremonial, almost as much so as the Roman Catholic. The altar is decorated with crosses and images, and the priest, arrayed in embroidered robes of velvet, celebrates high mass under that name. To maintain the ceremonial with decent splendour, as well as to support the clergyman in a respectable manner, it is necessary that the parishes should be of considerable size. There are in Norway 336 prestigilds or parishes; and many of these are exceedingly large, extending in some parts from the sea-coast to the Swedish frontier, and containing from 5000 to 10,000 inhabitants. This is certainly a low provision for religious instruction; but the people, generally speaking, are scattered all over the country, not clustered in towns and villages; and although individually they are not affluent, they are at least respectable, notwithstanding that as a whole they are poor. Under such circumstances, parishes must necessarily be large. There are five bishoprics in Norway, each of which has in it a suitable number of inferior clergymen. The patronage is in the hands of the five bishops and the Norwegian council of state, a committee of which has charge of all the affairs of the church. By judicious arrangements the abuse of patronage is prevented. Amongst the regular clergy there is one who has the superintendence over the concerns of four or five of the adjoining parishes; and the state of the church-property buildings, and the manner in which clerical duties are discharged, come under his cognizance. He communicates with the bishop of the diocese, and has a small allowance for performing these services, as dean or probst. This appears to be the only dignity in the church, with the exception of that of bishop. The incomes of the clergy are derived from tithes, commuted into a payment of grain, glebe farms, one of which the widow has for her life, offerings, and dues. These incomes in country parishes vary from 800 to 1600 dollars; but in large towns, or thickly settled parishes, they are higher. The bishops, says Mr Laing, have about four thousand dollars each. In proportion to the other professional classes in the country, the clergy are well paid, and the church has always been the first profession to which talent is naturally directed. The clergy are laborious and zealous in the discharge of their duty, the church service forming the smallest part of it. They have school examinations, Sunday schools, and other institutions for the promulgation of Christian knowledge. Mr Laing's impression is, that the Norwegian clergy are a highly educated body of men, being all acquainted with the literature of Europe, and some of them celebrated for their classical attainments. It is a peculiar characteristic of the Norwegian church, that there is no dissent from it; there are no sectarians in the country. This arises partly from the church having no temporal power, no political existence as a part of the state, no interests jarring with those of the other members of the community. In political rights and privileges the clergy are on a footing with the rest of the inhabitants, and are represented in the Storthing, like other citizens. The Lutheran religion is part of the state, but not the ministers who teach it. One chief cause of the influence of the ministers of religion, and the absence of dissent, is the high consideration in which the right of confirmation is held. The person who has passed this ordeal is regarded as having received a moral as well as a religious diploma, which capacitates him for an office of trust and responsibility. In connection with religion, we may mention the singular fact, that Bibles are remarkably scarce. Mr Laing could not obtain a copy of the Old or New Testament from the only bookseller in Drontheim, which contains 12,000 inhabitants, nor from the book-dealers at the fair of Levangor. The reason assigned for this remarkable deficiency in the sacred writings in a country attentive to religion, and sufficiently supplied with the catechism and the book of common prayer as used in the Norwegian church, is, that the Bible Society of London at one time sent over a great supply, and drove the regular dealers from the market by underselling them. In consequence of this they are now afraid to speculate in such a precarious stock.

Education is very generally diffused; but the standard of excellence is rather low, reading and writing constituting nearly the whole. It is provided for in the country parishes by an arrangement similar to that of Scotland. There are parochial schoolmasters, of whom some have fixed residences, and others live for one half of the year in one place, and for the other half in another. A small tax is levied from each householder, and every adult pays a small personal fee. There is a considerable degree of intelligence evinced in some of these communities; but the schools are too widely scattered over a thinly peopled country to be equally beneficial to all. It may be mentioned, that the clergy pay particular attention to the diffusion of education. The higher department of university education at Christiania is exceedingly expensive; and, besides, there is not such a demand for educated men in the medical, legal, and commercial professions, as in more densely-peopled and commercial countries, the tendency of which undoubtedly is to raise the standard of intellectual proficiency amongst all classes of the community. Those belonging to the learned professions are not numerous, because the demand is not great, and the supply is adjusted accordingly. The restrictions on the free exercise of trade and industry also operate with great force in depressing general education. Before a person can enter upon any medical or legal employment, before he can manufacture, buy, or sell as a merchant, he must obtain peculiar privileges from a corporate body. "As the expense of preparation," says Mr Laing, "and the small number of prizes to be obtained, place the higher and learned professions out of the reach of the main body of the people, as objects of rational ambition, for which they might endeavour to bestow superior education upon their children, so the restrictions and monopoly system shut them out from various paths and employments for which ingenuity, with ordinary useful education, might qualify them." With such a legislature as Norway possesses, it is to be hoped that these fetters upon the industry and intelligence of the country will not be allowed to remain much longer unremoved.

The press.

From the general diffusion of periodical publications, Mr Laing is led to infer that the Norwegians are a reading people. What is of great importance to the community is, that the press is by law perfectly free. There is no duty on newspapers, of which upwards of twenty are published; seven or eight in Christiania alone, and all in extensive circulation. Every little town has its local newspaper; and from the importance attached to local subjects there discussed, the bulk of the community are the purchasers, not the educated few. In type and paper they are superior to the French or German papers, and much ability is shown in conducting them. "Such newspapers as the American people read," says Mr Laing, "would not find readers in this country." There is no scurrility nor personal abuse displayed by those who write in them; yet the most entire freedom of discussion exists, public men and public measures being handled freely but decorously, and with a strict eye to the general good. There is no tax upon advertisements; and a measure to allow all periodical publications to be transmitted free of postage was lately negatived, only because the revenue of the post-office had been appropriated to certain specific purposes for the three years next ensuing. Some newspapers which are supposed to be particularly favourable to government are allowed by royal favour to pass free of postage at present, and no doubt is entertained that ere long all will be placed upon the same footing. A number of periodical and occasional works besides newspapers are published. There are two weekly magazines in great circulation; several monthly journals devoted to literature, antiquarian, agricultural, and military subjects; and in almost every newspaper there is the announcement of some new work or translation. Yet the literature which ought strictly to be considered as Norwegian is not yet of a very high order compared with that of other countries. But the mind of the country is advancing, and literature, which is young in Norway, will advance along with it.

Manners and customs.

The inhabitants of Norway are very polite in their manners, as well to each other as to strangers. They are partial to theatrical representations, so that the drama holds a high place in their estimation; and, besides the public theatres, there are societies of amateur performers in all the larger towns, and even in some of the villages. In music, dancing, and dress, the Norwegian females are by no means deficient. They have pleasing voices, and in every family of every station singing and dancing are constantly practised in the long winter evenings. Music is taught in the country by the organist attached to each parish. In the winter regular fairs are held, at which Swedes and Laplanders attend for disposing of goods. Christmas is kept in great style, and there are other festivals and various amusements which serve to relieve the tedium of winter and spring. The 17th of May, also, being the anniversary of their independence, is celebrated both at home and abroad by every Norwegian, and with marked propriety. Mr Laing gives a favourable account of the state of morals in Norway; but, without impugning so high an authority, if we are to take bastardy as a test, the statement is not borne out by the facts. The proportion of illegitimate to legitimate children is as one to five, which is as high as in London or Paris. But the evils entailed upon society by illegitimacy are partially alleviated by the state of the law in respect to this. Children are not only rendered legitimate by the subsequent marriage of the parents, as in Scotland, but the father, previously to his contracting a marriage with another party, may, by a particular act, legitimize them. The Norwegians are at all events a very hospitable, honest, industrious, and peaceable people.

Public improvements.

The government of Norway, aware of the value and importance of steam navigation, is making great and judicious exertions to promote it. This is a country where it is calculated to produce its greatest benefits, from the manner in which the peninsula is traversed by long arms of the sea, penetrating sometimes to its very centre. Steam-vessels are now seen plying on these fiords; they are commanded by naval officers; the fares are moderate; and in all that regards the comfort of passengers they rival our own. Roads and bridges are kept in a state of excellent order; a circumstance likely to happen in a country of proprietors, whose common interest it is to keep them in repair. There are no tolls in Norway; the principle of the farmers and others is to work in concert, and to keep up establishments for the common benefit.

The worst feature, perhaps the only thoroughly bad one, in the institutions of Norway, is, that the trade is not free. Each trade is monopolized by a sort of guild or fraternity, by which even country dealers are licensed. The pernicious effects of such a system we have sufficiently shown

Norwich.

when treating of the fisheries; and we shall close our account of this interesting country with the following observations, extracted from a work of great authority on such subjects:

"The principle of equal partition of land among all the children, retained in Norway from the earliest period, prevailed also in England before the conquest. A relic of it remains in the law of gavelkind, still existing in Kent. The different effects produced on society by the retention of that law in the one country, and its general disuse in the other, are remarkable. In Norway, chiefly by its operation, a high standard of sufficiency has been preserved among the middle and labouring classes. Population has been prevented from increasing too rapidly by the fear which people have of falling below the general standard. There has, therefore, been a continual prevalence and diffusion of ease and well-being. But, on account of the absence of great inequalities of condition, and therefore of many of the usual stimulants to exertion, society has been kept at a low level. Great social freedom has indeed always existed, in consequence of the land being in the hands of the mass of the people; but there has been a want of ability, until a very recent period, to combine for the preservation of their political independence. During their earlier history, their political liberties were often variable and uncertain. After the union of their crown with that of Denmark in 1380, it appears that the Danish nobility gradually encroached upon their privileges; for when, in 1660, the crown and the people combined against the nobility, and abolished the states in Denmark, a similar revolution also took place in Norway; and that country continued under absolute government until the establishment of its constitution in 1814. Their udal laws trained them in the management of their own affairs, and produced that feeling of self-respect which the possession of property, and of land in particular, is calculated to give. These, together with the civil institutions preserved or introduced whilst they were under the Danish crown, prepared them for the large measure of freedom to which they have now attained. The evil of their udal system is its tendency to obstruct the development of intellect, and to keep society stationary. But since 1814 they have made great progress. Stimulants to mental activity are now no longer wanting. Their continual collision with Sweden, the problem of their internal restrictions on trade and commerce, the routine of their government, and the wholesome struggles always arising in a free state, will supply them. Their land will become more productive, by the application of science to its cultivation; their trade will also be expanded. If we open our ports to their timber, which we may one day see accomplished, their wealth will increase. And, according to the experience of the last twenty years, wealth will not materially disturb the peculiarities of their social system."[1]

R. R. R.

NORWICH, a city of England, the capital of the county of Norfolk. No historical notices of the place are to be found during the period of the Roman government in this island. Its origin was during the Saxon heptarchy, when, in 446, a castle was first erected, on an elevation surrounded by water and marshes, which having become drained by natural, aided by some artificial means, gradually served as the site of the present city; its progress was slow, till Uffa, one of the kings of the East Angles, built a more solid castle in 575; and, the habitations having increased, it became the capital of the kingdom of the East Angles, which then comprehended the counties of Suffolk, Norfolk, and Cambridge.

It was captured by the Danes about an hundred years afterwards, and during the two succeeding centuries was often lost and won by that people, till Alfred the Great, in 872, had subdued those erratic conquerors, when he greatly improved the fortifications of the castle, which, having been originally of earth, he rebuilt with brick. In the reign of Ethelred, the Danes, under their king Swayne, again seized upon Norwich in 1003; but being expelled by Ethelred the next year, the city was left in a most desolate condition till 1011, when Swayne again returned, captured the castle, rebuilt the fortifications of the town, and conferred the government of it on one of his commanders, named Turkel or Turketel, who seems to have maintained himself in that post many years, and, notwithstanding occasional hostilities between the Danes and the Angles, to have contributed greatly to the advancement of the place, which was then constituted a borough. After the final expulsion of the Danes, in the latter part of the tenth century, the town increased with rapidity; much of the marshy ground was drained and built upon; and the first churches of stone were erected, some of which exist at the present time. Norwich had been created an earldom by Edward the Confessor in 1049; and in the reign of William Rufus the episcopal see was removed from Thetford, in 1094, when it became a city, but only received a charter of incorporation in the reign of Henry I., in the year 1100. The chief officer was then denominated *præpositus* or provost; but in 1152, by another charter, extended still further in 1189, the title of mayor was given, and the right of the citizens to elect that officer was conferred upon them.

This city was the residence of several of our monarchs at some periods during the reigns of John, of Henry III., and of Edward I.; and the cathedral having been finished in the year 1278, the latter sovereign assisted at the solemn ceremony of its consecration.

In the year 1336 the foundation of manufactures was laid in Norwich by a colony of Dutch and Flemish weavers, who had been driven from their own country by a great inundation. The goods they made were from woollen yarn, the best spinning of which was executed first at the town of Worsted in this county, and by the name of which thread made of wool has ever since been distinguished. By this manufacture the city rapidly attained a degree of opulence before unknown, and the traces of which have continued to the present day.

King Henry III., with his Queen, Philippa, visited the city, when a grand tournament was exhibited; and they repeated their visit two years afterwards, when a new charter was granted, which extended the powers and privileges of the citizens. In 1348 the city was afflicted with that dreadful visitation known as the plague, from which, it is said, more than 57,000 persons were carried off in seven months. Before that calamity the city is said to have contained 70,000 inhabitants, having sixty-nine parish churches, and eight religious houses. But it must soon have recovered from this visitation, as it is related that, two years afterwards, a grand tournament was held, at which Edward the Black Prince was present, for whose entertainment the citizens provided a magnificent banquet, at the expense of thirty-seven pounds four shillings and sixpence.

In the year 1422 the doctrines of the reformation made their appearance in Norwich, and several persons were

---

[1] Edinburgh Review, No. cxxxi. p. 60.

executed as Wickliffites, or, as they were then called, Lollards; and during the early part of the reign of Henry VII., between 1422 and 1448, many suffered severe whipping and other punishments, upon suspicion of entertaining the new opinions. These persecutions were continued at intervals till the reign of Edward VI., when, in the year 1538, the Protestant system being established by law, all the images in the cathedral and the parish churches were destroyed, and the different orders of friars and nuns in the religious houses were suppressed. On Trinity Sunday in that year the prior and monks in the cathedral changed their dresses for the habits of deans, prebends, and canons, and the Protestant worship was celebrated in it, and in all the parish churches within the city.

In 1549 this city was the theatre of a tumultuous insurrection, resembling that of the Jacquerie in France, and the peasants' war in Germany. It was at first an insurrection of the rural population, on complaints respecting the enclosure of common fields. As soon as numbers had been collected, they chose as their leaders two brothers of the name of Kett, one a tanner, the other a butcher; and on the 7th of July their numbers amounted to 16,000 men. They surrounded the city, and from thence increased their numbers to more than 20,000. Having established themselves near the city, the Ketts proclaimed themselves the king's deputies, and established a pretended court of judicature under a spreading tree, which they called the Oak of Reformation. Many gentlemen and clergymen were made prisoners by this rabble, and treated with the most barbarous cruelty. They made several attempts to force their way into the city, and succeeded in making some progress towards its reduction; but being repulsed, they, on their retreat, set fire to the houses in several places, so that some streets were consumed, and the whole city would probably have been rendered a heap of ruins, if an unusually heavy fall of rain had not checked the farther extension of the conflagration.

Whilst the insurgents still continued the siege, they were quarrelling amongst themselves, and committing the most atrocious acts of violence on the surrounding country, as well as on the persons of the gentry who were so unfortunate as to fall into their hands. They at length became masters of the city, though a small body of forces under the Marquis of Northampton had been sent to defend it. At length a more powerful body, commanded by the Earl of Warwick, made its appearance before Norwich. The first efforts of the royal troops were unsuccessful, and the rebels obtained possession of the artillery and ammunition of the Earl of Warwick, but were too ignorant of their use to improve the advantage they had gained. New troops were brought to the royal army, when a bloody attack, in which 3500 of the rebels were killed, decided the contest. A general pardon was proclaimed to all but the leaders, who were soon seized, and tried for rebellion; some were executed on the spot, but the Ketts were conveyed to London, and there convicted, but at length sent back to the place where their guilt had been incurred, and executed with great cruelty.

From the extinction of this rebellion, which, as before stated, commenced on the 7th of July, and was terminated on the 29th of August, the history of this city has nothing so peculiar as to make it an object of attention distinct from the general history of England.

Norwich is partly built upon a plain on the banks of the Wensum, a branch of the river Yare, which has been from time immemorial navigable for barges to its entrance into the sea at Yarmouth. Of late years a project has been executed for rendering this city accessible to vessels of considerable burden direct from the sea. This has been done by forming a canal ending in the lake, or, as it is provincially called, the Broad of Loathing, whence, by some excellently-constructed flood-gates, an opening into the sea at Lowestoff has been completed.

Norwich.

The city, built on the very gentle acclivity of a hill, is distinguished by one peculiarly striking feature; a large sugar-loaf hill of considerable elevation, which (whether formed by nature or by art, has been frequently a subject of dispute) stands in its centre. On the summit of that hill, towards the south-west, stood the ancient castle, of very remote but doubtful origin, though tradition, as before stated, has ascribed it to a king of the East Angles, who reigned about the year 575. It long continued strongly fortified, and, till more peaceful times have made such objects of less importance, served as the means of either protecting or overawing the city. Great alterations have been made on the level at the top of the castle hill at various periods; and, finally, since the year 1793, it is occupied with a pile of buildings as nearly resembling the architecture of the old castle as could be adapted to the purposes for which it is now used. Though the outside has a heavy and indeed gloomy appearance, the interior is appropriated with great judgment and taste as a county jail, a county hall, and an apartment for holding general county meetings.

As this castle hill covers a large space, and as the streets either converge from or wind round it, those in the vicinity, which are the scenes of the greatest activity, are both narrow and crooked, and have rather a gloomy appearance. This is indeed in some measure relieved by an extensive market-place, a large open oblong square, said to be the finest in England. This market is most abundantly supplied with provisions of all kinds, and of the best description, on Wednesdays and Saturdays. The spots for the different articles are kept separated into those for meat, for fish, for vegetables, and for poultry, butter, eggs, &c. The houses which surround the market-place are lofty and elegant, many of them have been recently new-fronted, and some rebuilt, and most of them are occupied by well-embellished shops. In the front of these shops, what is called the Gentleman's Walk was the first part of the city paved with flag-stones, and was long the chief promenade in the city.

At the northern corner of the market stands the guildhall, an ancient and large building constructed of black flint, with cornices, window-frames, and battlements of Portland stone. The assizes for the city and the county of the city are held in an appropriate apartment of this edifice, as well as the elections of members of parliament and other elective functionaries. The upper part of the building is a room supported by fluted pillars of the Corinthian order, designed for the justices of the peace of the city, having the mayor's council-chamber within it, with a large and two small windows of beautiful stained glass. It is adorned with portraits of former distinguished members of the corporation, and more especially by a naval trophy presented by Lord Nelson, containing, in a glass case, the sword of the Spanish admiral, delivered up to that hero at the great victory gained near Cape St Vincent on the 14th of February 1797.

St Andrew's Hall, a public building, chiefly used for the social meetings of the corporation, or other public bodies, is an ancient foundation; but in its present state it is a regular and beautiful structure, consisting of a nave and two side aisles, more than fifty yards in length and thirty in breadth. It is adorned with some portraits of former magistrates by eminent artists, set in elegant frames, carved with great labour, and highly gilded. Under the gallery, at the west end, is suspended the ensign of the French ship Genereux, presented by Sir Edward Berry, the brave captain of the Foudroyant, in the year 1800. Amongst the paintings in the edifice is a fine full-length of Lord Nelson, and two historical pictures by Martin, a native of the city;

Norwich.

one representing the story of Edward and Elenora, the other the execution of Lady Jane Grey. The Dutch congregation have the right of assembling here on Sunday for public worship.

The most prominent public edifices in this city are those for ecclesiastical purposes. The first of them is the cathedral, a venerable pile, one of the finest remains of Saxon architecture in this country. This building was originally erected under a Bishop Herbert, in the year 1069; and it has undergone various alterations and improvements at subsequent periods up to the present time. It is 400 feet in length, from the entrance door at the west to the east end. The west front is handsome and uniform; and the upper part is ornamented with four turrets of stone-work, and one large and two small doors. Over the centre door is a large Gothic window, extending the whole breadth and depth of the nave. The two transepts extend in length about 180 feet from north to south. The north front is ornamented with two pinnacles of stone, and over the middle door is a carved figure of Bishop Herbert, the founder. The south front has likewise two pinnacles of stone, between which, in the pediment of the roof, is a handsome dial. The interior, on entering the west front, exhibits a very pleasing appearance, arising from the uniformity and the neatness of the building, having a space of 204 feet to the entrance of the choir, which is fifty-four feet wide and seventy in height. The roof is of stone, supported by two rows of massive pillars, and is curiously arched, and carved full of small figures representing many passages of history from the Old and the New Testament. These figures are in a state of good preservation, although they have existed ever since the year 1463. The roofs of the north and south transepts also exhibit the same kind of curious workmanship. The whole of the roofs are highly esteemed by the curious, and it is said they are the only carvings of this kind that have existed so long, and been so perfectly preserved. The roof of the chancel is eighty-four feet high, and the arches and carved figures in it are very curious. The choir is spacious and beautiful; the stalls of the dean, of the vice-dean, archdeacons, prebendaries, and canons, as well as the bishop's throne and the chancellor's seat, are of Gothic carved work; and near them a temporary pulpit is placed for the weekly preacher. At the east end of the choir are four painted windows, the lowest representing the transfiguration, and the other some of the apostles, evangelists, and prophets. In the body of the cathedral are a number of monuments to the memory of distinguished ecclesiastics who have filled the different offices connected with this church. The tower rises in the centre of the building, at the meeting of the four roofs. The ceiling is there 100 feet in height, and the tower rises 140 feet above that. The outside is adorned with curious Gothic carved work, and is crowned with a battlement and four small spires. From the battlement a spire rises sixty-four feet, thus making the cross and weathercock at the apex 306 feet from the ground. From the low spot upon which it stands, it is not, however, a conspicuous object at a distance.

The cloisters adjoining to the cathedral excite much attention. It consists of the largest and most beautiful quadrangle in England, and was built in the year 1279. It is about 174 feet square, each of the four sides being twelve feet wide; the arches are Gothic, and the windows were once furnished with painted glass. The roof is full of historical figures, the subjects being taken from the gospel, the Revelations, and ecclesiastical history; and it is upwards of fifteen feet in height. At the south-west corner are two lavatories, ornamented with curiously carved work, representing the inveterate antipathy borne by the monks towards the secular clergy. The roofs contain no less than 418 historical figures.

The bishop's palace is a vast pile of building, very antique, but modernised in some degree at subsequent, and in the greatest degree in comparatively modern times. The principal entrance is through a large and ancient gateway, with an ornamented Gothic arch. The only object within deserving of notice is the chapel, a neat and spacious edifice of white stone, most neatly fitted up. The whole precinct of the cathedral is surrounded with a lofty stone wall, except on the eastern side, where it is bounded by the river.

The parish churches are more numerous here than in any other place in England, excepting the metropolis. Few of them deserve notice; some of them are small, and several of them but a few years ago were covered with thatch. The whole number is thirty-eight. One of the oldest, and by far the largest, is that of St Peter's Mancroft. It is a fine building, 180 feet in length and sixty feet in height, with north and south aisles each 120 feet long. The inside is much admired for the lightness of its construction, the slenderness of its pillars, and the number and size of its windows. It contains many, and some remarkably fine, monuments. In the tower is a ring of twelve musical bells put up by a voluntary subscription of the parishioners in 1775. They vary regularly in weight from six hundred-weights three quarters five pounds, to forty-one hundred-weights one quarter four pounds, weighing together nine tons four hundredweights twenty-four pounds. They are highly harmonious, and are commonly rung on festivals and holidays.

Besides these numerous churches, there are places of worship for two foreign congregations of Protestants, two Roman Catholic chapels, two Quakers' meeting-houses, and chapels for each grade of dissenters from the Socinians to the Huntingtonians.

The city is well supplied with benevolent institutions for the relief of distress. Bethel Hospital, for lunatics, is endowed; St Giles Hospital, an ancient establishment, provides for a hundred poor, equally divided between males and females; Doughty's Hospital, from the name of the founder, supports twenty-four aged men and eight women; the Girls' Hospital, united with the Boys' Hospital, and with an altered establishment, provides for a large number of both sexes, both in clothing and in maintenance; the Infirmary is supported chiefly by parochial assessments; the Asylum for Indigent Blind was opened in 1805, by the beneficence of an individual, and the aid of voluntary contributions; Cook's Hospital provides for ten aged females; and the Norwich Dispensary, founded in 1804, provides the poor with medicine and medical advice gratis. The voluntary associations for purposes of beneficence are the following, besides some of a private nature, viz. the Humane Society, for recovering persons apparently drowned; the Friendly Society, for the benefit of women in old age or sickness, administered by ladies, who distribute a large sum annually; the Friars' Society, which dispenses to the industrious poor the charity for clergymen's widows; the Benevolent Association, which has for its object the relief of decayed tradesmen; the Norfolk Benevolent Medical Society, and the Amicable Society of Attorneys, which relieve the distressed members and families of their respective professions; and the Society of Good-Will, which aids those who are not entitled to any parochial relief.

Amongst charities for educating the poor, the St George's Company, an old institution of the year 1700, must be noticed. It is chiefly supported by voluntary contributions, and educates some hundred boys and girls, who attend public worship in six parish churches. Almost every one of the various dissenting congregations has either Sunday or daily schools attached to their respective places of divine service.

One establishment, although supported by and extende to the whole county of Norfolk, is the County Hospital, witl out St Stephen's gate, erected in 1772, but enlarged at a subsequent period. A great number of patients are continually admitted and relieved by this excellent institution. The most eminent medical men attend daily, and the hospital is at all times open for accidental cases.

For objects of amusement, Norwich has an assembly-room, a neat building, erected in 1756; and a theatre, considered as one of the most complete in the kingdom out of London, in which a company perform a few months in every year.

The population of Norwich in 1801 amounted to 35,252, in 1811 to 35,338, in 1821 to 50,190, and in 1831 to 61,110. But there are portions of some of the parishes beyond the boundaries of the city, though forming part of the suburbs. Thus, in 1831, the parish of Hellesdon contained sixty-one inhabitants beyond the city boundaries, St James' had 1669, and Thorpe had 940; thus making the population at that period amount to 63,770. As the increase up to the present time has been as great as in the preceding ten years, the population at the present time, 1837, must exceed 70,000 persons.

Norwich has been the seat of manufacturing industry from a very early period, the commencement of which has been remarked in the historical notices of this article. The long disturbances in the Netherlands, and the persecutions under the Duke of Alva in particular, produced immigrations from thence in greater number, and much more important, than those which had preceded that period; and the immigrants received the greatest protection from the government of Queen Elizabeth. The goods fabricated by these people were chiefly of wool; but some were made from flax and from hemp. The woollens received appropriate names, the exact significations of which are now nearly lost. Soon afterwards a peculiar fabric was produced, from a mixture of silk or of mohair with the wool. This gave a great impulse to the trade, and produced a considerable demand for the great markets of Frankfort, Leipzig, and others in the north, and for Spain, Portugal, and Italy in the south. At the beginning of the eighteenth century, about the year 1720, this trade was at its zenith. Almost the whole female population of Norfolk and Suffolk was employed at the spinning wheel; and though 50,000 tons of wool were used, it was found necessary to draw supplies of yarn from other districts. The establishment of manufactures in Yorkshire, where coals, provisions, and labour were cheaper than in Norfolk, gave a heavy blow to the trade of the city; which would have been more severely felt, but for the fluctuations of fashion having created a greater demand for bombazines, an article which had been early made there, but had at first languished. The Yorkshire workmen, and the substitution of machinery for female hands, reduced the making of the ancient kinds of goods to a low point; and that was chiefly maintained by the East India Company purchasing annually a very large quantity of camblets for the China market. During the period from 1700 to 1800, the population of Norwich declined till towards the end of the century, when some new manufactures, and a great revival in the bombazine trade, gave an impulse, the effect of which has continued with increased force to the present day. The introduction of the shawl manufactory, one of the chief causes of the present prosperity, took place about the end of the last century; and the fabric has gradually improved till it has almost supplied the whole trade of the kingdom, besides furnishing much for foreign markets. Besides this trade, and the making of bombazines, there are some of silk goods produced, and smaller manufactures of cotton and hempen linen. The malting is a considerable trade; and the corn market, from the easy connection with London through Yarmouth or Lowestoff, is one of the most extensive in the kingdom. It appears by the official returns of 1831, that there were in the city 3752 males above twenty years of age employed in manufactures. According to the returns of the same year, the whole number of the families within the city was 15,572, of whom 9174 were chiefly employed in trade, manufactures, and handicraft; 509 in agriculture; and 4889 not comprised in either of the two preceding classes.

The relative extent of trade in different towns may be in some measure determined by the amount of the postage of letters collected in them. In this view, Norfolk stands the ninth in the list of English towns, being next after London, Liverpool, Manchester, Bristol, Birmingham, Leeds, Hull, and Sheffield; and the sum collected having amounted in the year 1836 to L.9557. 10s. 3d.

The corporation of Norwich, before the municipal reform law was enacted, consisted of a mayor, a recorder, two sheriffs, twenty-four aldermen, and sixty common-council men; but by that law, instead of four wards, as formerly, it is now divided into eight, and has sixteen aldermen and forty-eight common-council men, chosen by the inhabitants, and justices of the peace and a recorder nominated by the crown. This city, as before, returns two members to the House of Commons, chosen by a very numerous body of resident electors, comprising, besides the ten-pounds householders, many hundreds of freemen. The title of Earl of Norwich was conferred upon the Scotch Duke of Gordon; but that title, as well as the dukedom, is now extinct.

NOSE, the organ of smell. See ANATOMY. The uses of the nose are, exciting in us the sense of smelling, and serving in the great office of respiration, as well as in modelling the voice, receiving the abundant humours from the eyes, and adding to the beauty of the face. The nose was by the augurs particularly attended to in forming conjectures concerning future good or ill success. The tingling of the right or left nostril, for instance, was thought to indicate different things, as it happened to different sexes, or to persons in different conditions.

NOSOLOGY is a Greek word signifying a discourse or treatise of diseases, otherwise called *pathology*. The importance of a comprehensive and accurate nosology has been long and generally allowed. Baglivi, Boerhaave, Gorter, Gaubius, and Sydenham, have expressed their desire for a work of this kind, the great object of which should be to fix the pathognomonics of every disease, or to dispose all diseases into certain classes, orders, and genera, founded on distinctions taken from the symptoms only, without regard to remote or proximate causes.

NOSTOCH, SHOT STARS; *tremella nostoc* (Lin. *Spec. Plant.*; Dillenius, *de Muscis*, tab. 10, fig. 14; *Flor. Danica*, tab. 885, fig. 1); *tremella intestinalis vel mesenterica* (Lin. *Spec. Plant.*; Dillen. *de Mus.* tab. 10, fig. 16; *Flor. Danic.* tab. 885, fig. 2). The substance in question is not unfrequent in England, and in other parts of Europe, after rains, both in spring and autumn. Very large spots of it are seen in gravelly soils, and particularly on the tops of hills and on open downs, and it is often found on gravel walks. It is met with in some of the old authors, under the name of *nostoch*, as in Paracelsus and others; and the alchemists fancied there was something wonderful in it, and that it would afford a menstruum for gold. Nostoch is said to be a word synonymous with *Jaculum alicujus stellæ, vel potius ejus repurgatione dejectum quid in terram, flos aëris, fragmentum nimbi*; as this substance was believed to fall from the sky, along with the meteors which we often see, and call *falling-stars*. Hence the country people in Sweden have called it *sky-fall*; and in England it is known by the name of *witches' butter*, in common with some of the gelatinous liver-worts.

Paracelsus, Helmont, and others, however, ranked it with the *terniabin*, or manna, and thought it dropped, as the lat-

Nostradamus.

ter did, from heaven. It is described, and the chemical analysis of it given, by M. Geoffroy, in the Memoirs of the Academy of Sciences for 1708, and is there said to yield, besides an acid phlegm, a portion of concrete volatile salt and some fixed salt. The distilled water from it was believed by some to possess singular virtues in allaying pains of the joints; but there is certainly no ground for attributing to it any extraordinary qualities. Since the days of Paracelsus it has been considered as a vegetable production; but the botanists have had difficulty in assigning to it its place or genus in their several systems.

Naturalists had, however, for some years begun to doubt whether the substance in question was of a vegetable or animal nature, when at length the latter opinion received a strong corroboration from the observations of Mr Platt of Oxford, in a letter printed in the Gentleman's Magazine for 1776.

"From a child," says he, "I remember seeing the meteors shooting in the air, which appearance, by my comrades, was called *star-shooting*, believing the stars no larger than their apparent magnitude. This jelly-like substance, mentioned in your magazine, was believed to be the dross of these meteors, and took the name of *star-shot*, which passed for certain with me till I had arrived at the age of twenty-four, when I was engaged in business that required my frequently passing over both meadows and pasture-grounds, where in spring and autumn I saw many portions of this supposed alga or nostoch, but never more than one or two contiguous, mostly near the water, when the meadows were or had been just before flooded. My conjectures were various, until I saw a crow pecking of something in a field, which I heard to cry; when turning my horse to the place, I found a frog of the common size, which the crow (of the carrion kind) would soon have killed and gorged, had I not disturbed her, and chased her away.

"About this time I found in a meadow the bowels of a frog indigested, and compact as the chitterlings of a calf or pig, but white as the paper I write upon, though not translucid. I took it up and placed it in a paper exposed to the air, leaving it in some grass where I found it, till my return that way in three days' time, when I saw it changed to that tremulous jelly-like substance, the alga or star-shot. I was much pleased with this discovery, and took it home in my pocket wrapped in a paper, where I showed it to a society of young persons of which I was a member, who agreed with my sentiments of its being the indigestible part of a frog disgorged by some bird of prey.

"To corroborate my sentiments of this alga being the bowels of a frog, I luckily saw some of it lying by the side of a brook, where I lighted and took it up, and to my great surprise found attached to the jelly the head, heart, liver, and one leg of the frog, which had been, I presume, disgorged by some carrion crow, who frequented the flooded grounds to pick up worms and other vermine. There was also some of it found on an apple-tree at Wyston Magna, near Leicester, where I then lived, which, no doubt, was disgorged by some owl."

Dr Darwin, in his Poem on the Loves of the Plants, is of the same opinion with Mr Platt, that these gelatinous substances are of an animal nature; and that the different appearances they put on are owing to various circumstances, viz. the different birds who feed on frogs, the quantity they devour at a time, and the state of digestion before they are voided.

NOSTRADAMUS, Michael, an able physician and a celebrated astrologer, was descended of a noble Provençal family, and born on the 14th of December 1503, at St Remy, in the diocese of Avignon. By his grandfather he was initiated in the study of the mathematics, and he afterwards completed his courses of humanity and philosophy at the college of Avignon. Having repaired to Montpellier, he there applied himself to physic, till being forced away by the plague in 1525, he took his route towards Toulouse, and passed on till he reached Bordeaux. This course occupied him five years, during which he undertook the cure of all such patients as were willing to put themselves under his care. After this he returned to Montpellier, and, having been created doctor of his faculty in 1529, revisited the places where he had before practised physic. At Agen he contracted an acquaintance with Julius Cæsar Scaliger, which induced him to make some stay in that town, where he married; but having buried his wife, and two children which she had brought him, he quitted Agen after a residence of about four years. On his return to Provence, he established himself first at Marseilles; but his friends having provided an advantageous match for him at Salon, he, in 1544, transported himself thither. In 1546, Aix being afflicted with the plague, he went thither at the solicitation of the inhabitants, and proved of great service; so that the town gave him a considerable pension for several years after the contagion ceased. Returning afterwards to Salon, he became a recluse, and employed his leisure in applying to his studies. He had for a long time occasionally followed the trade of a conjurer, and now he began to think himself inspired, nay, miraculously illuminated with a prospect into futurity. As fast as these illuminations had discovered to him any future event, he entered it in writing, in enigmatical prose sentences; but revising them afterwards, he thought the sentences would appear more respectable, and would savour more of a prophetic spirit, if they were expressed in verse. This opinion determined him to throw them all into quatrains, and he afterwards ranged them into *Centuries*. When this was done, he hesitated about making them public, till reflecting that the time of many events which he had foretold was very near at hand, he determined to print them. This he did with a dedication addressed to his son Cæsar, an infant only some months old, in the form of a letter or preface, dated the 1st of March 1555. This edition, which includes seven *Centuries*, was printed by Rigault at Lyons. He prefixed his name in Latin, but gave to his son Cæsar the name as it is pronounced, *Nôtradame*.

The public were divided in their sentiments respecting this work. Many looked upon the author as a simple visionary or a fool; whilst by others he was accused of the black art, or magic, and treated as an impious person, who held a commerce with the devil. But there were not wanting persons who believed him to be really and truly endowed with the supernatural gift of prophecy. A few remained in suspense, and refrained from giving any judgment at all respecting his pretensions. But Henry II. and Catherine of Medicis his mother, having resolved to see the prophet, he received orders to that effect, and immediately repaired to Paris. He was very graciously received at court, treated with extraordinary respect, and gratified with a present of two hundred crowns. He was afterwards sent to Blois to visit his majesty's children there, and report what he should be able to discover concerning their destinies. No doubt he exerted himself to the utmost on this occasion, but the precise nature of his prognostications is not known; it is certain, however, that he returned to Salon loaded with honours and presents. Animated with his success, he augmented his work from three hundred quatrains to a complete milliad, and published it in 1558, with a dedication to the king. But that prince having died the next year, of a wound which he received at a tournament, the book of the prophet was immediately consulted; and in the 35th quatrain of the first century this unfortunate event was found predicted in the following verse:

Le lion jeune le vieux surmontera,
En champ bellique par singulier duel,
Dans cage d'or les yeux lui crevera,
Deux classes une puis mourir, mort cruelle.

So remarkable a prediction added new wings to his fame, and he was shortly afterwards honoured with a visit from Emanuel duke of Savoy, and the Princess Margaret of France his consort. From this time Nostradamus found himself overburdened with visitors, and his fame daily increased. Charles IX. on visiting Salon, was eager to see him. Nostradamus, who then waited as one of the retinue of the magistrates, being instantly presented to his majesty, complained of the little esteem his countrymen had for him; upon which the monarch publicly declared, that he should hold the enemies of Nostradamus as his own, and further desired to see his children. Nor did that prince's favour stop here. Not long afterwards, in passing through the city of Arles, he sent for Nostradamus, and presented him with a purse of two hundred crowns, together with a brevet, constituting him his physician in ordinary, with the same appointments as the rest. But the prophet enjoyed these honours only for the space of sixteen months, having died at Salon on the 2d of July 1566. Besides his Centuries, we have the following compositions of Nostradamus: A treatise *de Fardemens et de Senteurs*, 1552; a Book of singular Receipts, *pour Entretenir la Santé du Corps*, 1556; a piece *des Confitures*, 1557; and a French Translation of the Latin of Galen's Paraphrase, exhorting Menedolas to apply himself to study, especially to that of physic, 1552. Some years before his death, he published a small instruction for husbandmen, showing the best seasons for their several labours, which he entitled The Almanac of Nostradamus. Lastly, after his death there came out the eleventh and twelfth Centuries of his Quatrains. It is to these productions that the following pungent distich was applied:

Nostra damus cum falsa damus, nam fallere nostrum est,
Et cum falsa damus, nil nisi Nostra damus.

NOTÆ, signs used in writing, which have the force of many letters. This contrivance for expedition is of great antiquity. It was known to the Greeks, and from them passed to the Romans. By whom the invention was brought to Rome has not been precisely ascertained; but the most general opinion is, that in matters of importance Tully first made use of notes or short-hand writing when Cato delivered an oration in opposition to Julius Cæsar relative to the conspiracy of Catiline. Cicero, who was at that time consul, placed *notarii*, or expert short-hand writers, in different parts of the senate-house, to take down the speech; and this was the first public occasion which we find recorded of employing short-hand writers amongst the Romans. It is unnecessary to observe, that the name of *notary*, still in use, was derived from this practice. There were three kinds of notes for short-hand writing used by the ancients, either for despatch or secrecy. The first and most ancient was that of hieroglyphics, which are rather images or representations of things than of words. The second species were called *singulariæ*, from their expressing words by single letters. Sertorius Ursatus has compiled a very copious collection of such abbreviations. The third kind were called *notæ Tironianæ*, from Tiro the freedman of Cicero, who was particularly skilled in his art; and it is to him that we are indebted for the preservation of Cicero's letters, of which a great part still remain, one entire book having been addressed to Tiro himself.

It appears that notes were in frequent use amongst the Romans, and continued to be employed till the tenth and eleventh centuries. We have indeed but few books remaining which are written in short-hand; but this is not surprising, when such was the unhappy situation of early times, that either superstition condemned them to the flames as the works of impious magicians, or they were left, through ignorance and stupidity, to be devoured by vermin. It is probable, however, that there are still extant writings of this sort, which might contribute to enrich the republic of letters.

There are several manuscripts and instruments written in these kinds of *notæ* in the royal library of Paris. In the year 1747, the learned and ingenious M. Charpentier engraved and published at Paris a capitulary, and fifty-four charters of Louis the Pious, emperor and king of France, written in the *notæ Tironianæ*. To this work the learned editor has prefixed an *Alphabetum Tironianum*, together with a great number and variety of notes or marks for the different parts of speech, and rules for acquiring the art of writing in this kind of notes. Valerius Probus, in his book *De Litteris Antiquis*, explains many of the characters used by the short-hand writers; and there is a dictionary of them published by Gruterus.

NOTARII, persons employed by the Romans to take, by means of *notæ*, trials and pleadings in their courts of judicature, or to write as amanuenses from the mouth of an author. These *notarii* were of servile condition. Under the reign of Justinian they were formed into a college or corporate body. *Notarii* were also appointed to attend the prefects, in order to transcribe for them. There were likewise *notarii domestici*, who were employed in keeping the accounts of the Roman nobility; and when the empire became Christian, there were notaries for ecclesiastical affairs, who attested the acts of archbishops, bishops, and other spiritual dignitaries. We find ecclesiastical notaries at Rome under Pope Julius IV. and also in the church of Antioch about the year 370. From these notaries was derived the office of chancellor to the bishops; and afterwards almost every advocate was admitted a notary.

NOTARY (Notarius) signifies a person who takes notes, or frames short draughts of contracts, obligations, charter-parties, or such other writings. At present we call him a *notary public*, because he publicly attests deeds or writings, in order to make them authentic.

NOTATION, in *Arithmetic* and *Algebra*, the method of expressing numbers or quantities by signs or characters appropriated for that purpose. See Arithmetic and Algebra.

NOTES, in music, characters which are used, in writing or printing, to mark the pitch and the duration of the sounds of any musical composition. These characters or signs of notation have varied much at different times. Many alterations of those now generally received have been proposed, but not adopted. *Numerical* and *literal* methods of expressing musical sounds have been repeatedly proposed; but it seems that these are even more complicated than the signs in common use. A musical short-hand, constructed of alphabetical letters, was proposed many years ago in France, but rejected; although in numerous cases of simple melody and harmony it might be very useful in saving space to publishers of books. As to the notation of music in ancient and modern times, see Padre Martini, Hawkins, and Burney, and especially Mersenne regarding the *entablature* of some musical instruments now disused. See Music.

Note is likewise used to signify a mark made in a book or writing, where there occurs something remarkable and worthy of particular notice; as also an observation or explication of some passage in an author, added in the margin, at the bottom of the page, or elsewhere. In this sense it stands contradistinguished to *text*.

Note is also a minute, or short writing, containing some article of business. In this sense we say, promissory note, note of hand, bank-note, and the like.

NOTHUS signifies *spurious* or *bastard*; and hence it is

Notion || Nottingham.

figuratively applied by physicians to diseases which, though in respect of a similitude of symptoms they have the same denomination as some others, yet are of a different origin from them.

NOTION, a word which in common language is considered as of the same import with idea. See METAPHYSICS.

NOTITIA, in literary history, a book which gives an account of a particular country, city, or other place. Such are the *Notitia Imperii Romani*, the *Notitia Romæ Antiquæ*, and other similar works.

NOTO, a city of the island of Sicily, in the kingdom of Naples, the capital of the province of the same name, 149 miles from Palermo. It stands on a rocky hill, in a fine but unhealthy situation. It has elegant streets, with noble churches and convents, and forms one of the most respectable places on the island; whilst the surrounding soil, though much of it is neglected, is of abundant fertility. Its port is Avola, about seven miles distant. It contains 1958 houses, and 13,300 inhabitants.

NOTO, *Val di*, one of the three valleys or provinces into which Sicily is divided, and which lies between the sea, the Val di Demona, and the Val di Mazara. Noto is the capital town.

NOTTINGHAM, a large market-town of England, the capital of the county of the same name, in the centre of England. It is a place of great antiquity, deriving its name from the Saxon word *Snottingaham*, which is descriptive of its position as a retreat in rocks, since there were formerly many, and are still a few, caverns, cut on the soft rock on which its castle was built. It is by some antiquaries asserted that it was once a Roman station; but that is a subject of controversy. The earliest records notice some incursions of the Danes about 866; but they appear to have received a check from the town, and a defeat near it from King Alfred, who afterwards made it the winter-quarters of his army. William the Conqueror erected a castle, and constructed fortifications so strong as to render the place impregnable against any of the methods of attack which were then known. King Richard Cœur de Lion assembled a parliament in this place previously to his departure for the Holy Land, and another soon after his return from Palestine. It was from Nottingham that Richard III. marched forth to his fatal battle of Bosworth Field. There Charles I. erected his royal standard at the commencement of the civil war, at the spot which is now covered by St James' Church. The Castle of Nottingham, defended by the royalists, was besieged by the parliamentary forces under the command of Colonel Hutchinson, to whom, after a brave defence, it at length surrendered, the particulars of which are related in a most interesting manner by the wife of that officer. When Cromwell had attained supreme power, he ordered the fortifications to be destroyed and the castle to be dismantled. At the beginning of the present century, this town and neighbourhood were distinguished by the riotous disposition manifested amongst the lower orders, who acquired the denomination of Luddites, and were excited to destroy much of that machinery by the aid of which the town subsequently attained to its present high degree of affluence. These disturbances were quelled by the power of the law, and some wholesome severities; but it caused the removal of many of the capitalists, and a large portion of the trade, to distant and more tranquil districts. During the excitement respecting parliamentary reform in 1832, a very violent spirit was manifested, which led to the destruction of a silk-mill in the neighbourhood, the burning of the ancient castle belonging to the Duke of Newcastle, and outrages upon private houses. These disturbances led to a few exemplary punishments, and some heavy burdens on the town, to indemnify those whose property had suffered by the riots.

Nottingham is finely situated upon the side of a hill overlooking the valley of the Trent, and near to the south-western extremity of what was formerly the forest of Sherwood, once famous as the resort of the celebrated Robin Hood, but now a well-cultivated district. The environs of the town are picturesque and beautiful; and there is a delightful walk on the bank of the river Leen, having a fine view of the south front of the castle, and of the gardens, which were formerly the fish-ponds belonging to that edifice. The windings of the river Trent have also a great effect on the whole scenery.

Some of the old streets are narrow, but in the great extension of the place of late years some new and spacious avenues have been built, and much improvement has been judiciously effected. The market-place is one of the finest in England. It is spacious, occupying an area of 27,515 square yards, or rather more than five acres and a half. It is well paved, and admirably adapted for the purpose of the three weekly markets held in it on Wednesday, Friday, and Saturday, the last of which is the principal one. At the east of the market-place stands the Exchange Hall, which is a noble-looking building. The pediment is crowned with a well-proportioned pedestal, on which stands the figure of Justice. On the pediment are the town arms, with an oak branch on one side, and an olive branch on the other; and underneath it, with a clock intervening, is a handsome Venetian window, ornamented with two elegant Ionic columns, which lights the spacious room within it. That apartment, when the temporary doors which divide it are thrown open, is 123 feet long, thirty wide, and thirty high, with an arched ceiling. It is used for public dinners, at which more than 400 persons can be commodiously seated, and also for public meetings. This room was nearly destroyed by an accidental fire in 1836, but has been restored and further beautified. One part of the building is appropriated to magisterial business, and another is occupied by the Artisan's Library; an institution possessing some thousand volumes, which are lent out to members, who pay seven shillings and sixpence on admission, and one shilling and sixpence quarterly. Underneath the Exchange there are a few shops in front, but the principal part of the ground-floor is appropriated to shambles. In another part of the market-place is the Subscription Library, containing a large collection of valuable books; and a news-room; a cabinet of mineralogy, with sculpture, maps, and portraits of eminent individuals connected with the town, amongst whom are Colonel Hutchinson, Lord Byron, Sir Richard Arkwright, and others.

The other civic buildings are the county jail and hall, a commodious but not elegant structure; the house of correction, which stands on the site of a convent of the hospitallers of St John of Jerusalem; the town hall and town jail, where the borough assizes and sessions, and the mayor's and sheriff's courts, are held; the assembly-room, a very elegant building, just erected and fitted up with much taste; and the free grammar school, in which about a hundred boys are gratuitously instructed in Greek and Latin.

The edifices for religious worship are in about the same proportion to the number of the inhabitants as is seen in other places which have increased with similar rapidity. St Mary's is usually denominated the mother church of the town, from its priority of erection. It resembles a cathedral more than a parish church in its extent, its architecture, and its decorations, and is the most striking object in the place, when viewed from what is called the high pavement. It stands on an elevated spot, and is said to be nearly seventy feet above the level of the meadows near the town. The date of the erection is unknown, but is said to have been in the fifteenth century. It is in the form of a cross, and has a handsome square tower, in which there is a musical peal of ten bells. The length of the structure in the inside is 216 feet, the breadth in the centre ninety-seven, at the west end or principal entrance sixty-seven, and in the chancel twenty-nine feet. The height of the tower is 126 feet, and that of the side aisles sixty feet. The porch on the south side is a very ancient piece of workmanship, on the fluting of the pediment of which were sculptured red and white roses, some traces of which may even yet be discovered. In the west gallery there is an excellent organ of great power, supported by two Tuscan columns, over which is a picture of David playing on his harp. There are in this church many monumental inscriptions on tombs of the family of the Earls of Clare, and one of an Earl of Meath, and the mausoleum of the family of the Wrights.

Besides the mother church, there are provided for the adherents of the established worship the following edifices, all of them capacious, and appropriately finished, viz. St James', St Nicholas', St Paul's, and St Peter's. The chapels of various sects are numerous, amounting to twenty, but some of them are very small. They are classed thus: Independents; Baptists, two subdivisions; Wesleyan Methodists, three subdivisions; and one each for Unitarians, Roman Catholics, Quakers, Huntingtonians, and Inghamites or Sabellians.

The charitable institutions depending on endowed foundations or on voluntary contributions are numerous. The General Hospital, built in 1781, contains about two acres of land, given partly by the Duke of Newcastle, and partly by the corporation. It is supported chiefly by subscriptions, and usually contains about 120 patients; whilst between five and six hundred are out-patients, receiving medical advice and assistance. The General Lunatic Asylum is a modern and spacious brick building, erected in 1810, at an expense of nearly L.20,000. There are extensive courts, gardens, and places for recreation, and the whole economy of the place is constructed in such a manner as may best contribute to the recovery or the welfare of the miserable inhabitants. Labray's and Lambley's Hospitals are small asylums for aged widows; and Collins' Hospital is a splendid charity, founded by one of the Smith family of the town, of which Lord Carrington is the present head. It consists of twenty-four small but convenient dwellings for as many poor widows, each of whom receives four shillings weekly, and two tons and a half of coal every year. From the same endowment Carrington Street Hospital has lately been built, where twenty poor persons are comfortably accommodated. Plumtree Hospital, founded by a family of that name, since transplanted into Kent, in the year 1392, but twice repaired since, viz. in 1650 and 1751, has been rebuilt under an act of parliament passed in 1823. Thirteen aged widows are provided with comfortable dwellings within the house, and allowed six shillings weekly, whilst thirty others, called out-pensioners, receive ten pounds a year. Willoughby's Hospital contains nineteen tenements, the inhabitants of which receive a small pension. Wooley's Alms are dwellings for six poor persons; and Bilby's Almshouses for eight persons, who have each a loaf weekly, and two tons of coal at Christmas. Warser's Gate Hospital gives apartments to six, and Hanley's to twelve poor persons.

The other public edifices that deserve notice are the Barracks, built in 1792, a handsome building, with well-contrived apartments for officers and for the privates, and suitable stabling for three troops of horse; the Riding School; a small theatre, never long opened nor much attended; the water-works, in two parts of the town; the gas-works; and the bridge over the river Trent after that stream has been augmented by the waters of the Dove and the Derwent.

The population of this town in 1801 amounted to 28,861, in 1811 to 34,253, in 1821 to 40,415, and in 1831 to 50,680. This great increase, arising from the progressive extension of its manufacturing industry, is not, however, confined within the limits of the town, but is exhibited in the villages either contiguous to it and forming its suburbs, or at a few miles distance. Thus Snenton, which conjoins the town, contained in 1801 but 558, and in 1831 it had 3605 inhabitants; Radford, a parish within a mile of Nottingham, had in 1801 but 2269, and in 1831, 9806 persons; Lenton, another parish, in 1801 had 893 inhabitants, and in 1831, 3077. There are other parishes near to it, in which a similar progress has been making, so that Nottingham, with its dependencies, may be estimated, supposing that the increase since 1831 has been at the same rate as in the previous periods, to have more than 70,000 individuals. According to the account of Mr Rickman, the males above twenty years of age employed in the stocking and lace trade are, in Nottingham 4740, in Radford 1300, in Lenton 300, at Snenton 430, and at Beeston 300.

Nottingham.

The Trent, which is navigable up to the town, and the various canals which branch from that river, afford the means of easy communication with every part of the kingdom.

The chief accumulation of capital in the town and its vicinity has been from its manufactures. The most ancient, and still the most extensive, is that of stockings. The earliest introduction of that neat piece of machinery, the stocking-frame, at nearly the same period into Leicester and Nottingham, gave to those towns a superiority in fabrication, which has subsequently been maintained, and which has nearly superseded the domestic manufacture of knitting stockings. The stockings of the two towns, made either from wool, thread, cotton, or silk, are to be seen in every part of the world, and far excel in beauty and cheapness any that are made elsewhere in imitation of them.

The prosperity of Nottingham has, however, been advanced in a prodigious degree by a new manufacture executed by machinery, analogous to that of the stocking-frame, but contrived with a greater portion of mechanical ingenuity. This article of commerce is known by the name of bobbin net. It generally resembles lace, and has in a great degree supplanted that pillow lace for which Flanders, France, and some counties of England were once highly celebrated.

Although this trade originated at Nottingham, yet the riotous disposition of the workmen called Luddites (which has been already noticed), who opposed all those improvements in machinery to which the extension of this trade has been indebted, caused many of the capitalists to remove their establishments to other and some very distant counties. Yet, notwithstanding such removals, and the rivals thereby created, the trade here has gone on increasing, and is still most extensive in and around Nottingham. Our limits do not admit of tracing the various steps of improvement with great minuteness. At first, only plain nets were made, then quillings were introduced, and afterwards figured or fancy patterns were produced. The two last are the highest priced, and the chief object of the manufacturers here. The number and description of the machines in January 1836 were thus dispersed:—In Nottinghamshire, 372 for plain nets, 1006 for quillings, and 784 for fancies; in Leicestershire 207 for plain, thirty-seven for quillings, ninety-nine for fancies; in Derbyshire 192 for plain, forty-nine for quilling, fourteen for fancies; in Devonshire, Somersetshire, and the Isle of Wight, 654 for plain, thirty for quilling, 103 for fancies. Total for plain 1425, for quillings 1122, for fancies 1000. The improvement made by the introduction of the quilling and fancy nets has caused additional capital to be invested in machinery, and the employment of from 1500 to 2000 additional

Nottinghamshire.

workmen; and the above statement shows that this benefit has principally fallen to the share of Nottingham.

The following calculation, made by Mr W. Felkin, will show, in a national point of view, the great value of this apparently minute branch of industry. That gentleman estimates that, in the year 1835, there were used in this trade 1.850,000 lbs. of sea-island cotton wool, valued at L.185,000, and 25,000 lbs. of silk, valued at L.40,000. The produce of these raw materials, and their disposal, are stated by the same person thus: Home consumption for nets, L.320,000; for quillings, L.210,000; for fancies, L.580,000; total, L.1,110,000. Foreign trade, for nets, L.340,000; for quillings, 282,000; for fancies, L.480,000; total, L.1,102,000.

The plain nets made in the other parts of the kingdom are mostly sent to Nottingham in the rough state, where they receive the finishing operations of gassing, bleaching, and dressing. The amount of these was, in the year 1835, L.328,000; so that this town, besides the profit upon the goods manufactured in and near it, gains a considerable share of the profit upon the goods made by their rivals.

The net wages earned by men vary from twelve to thirty-five shillings a week, according to the kind, the width, and the speed of the machines at which they are employed. Sixteen shillings is about the average. Wages to women vary from three to twelve shillings, as they may be occupied, but average about six shillings a week. Children are paid from one to four shillings, and can be useful as embroiderers, or in mending and winding. Mr Felkin says it is difficult to estimate how many persons altogether are employed in the various departments of this flourishing trade.

Besides the staple trades, there are, in and around the town, several large factories for spinning and weaving cotton goods.

Nottingham has been celebrated for its ale, the qualities of which have been the theme of song. It is still good, and very potent. Its excellence has been attributed by some to the good quality of the barley grown in the neighbourhood, by others to the purity of the water, and by many to the excellent cellars scooped out of the rock with which most of the good houses are furnished.

This town returns two members to the House of Commons. The freemen, who were formerly the sole electors, are still numerous, but are exceeded in number by the ten-pound voters.

By the municipal corporation reform law passed in 1835, this town is to continue a corporation, is divided into seven wards, and has a mayor, fourteen aldermen, and forty-two councillors, with twelve justices of the peace appointed by the crown.

NOTTINGHAMSHIRE, an inland county of England, bounded on the north by Yorkshire and a part of Lincolnshire, on the east by Lincolnshire, on the south by Leicestershire, and on the west by Derbyshire. It is of an oval figure, with its narrowest end towards the north. Its greatest length is about fifty miles, and its greatest breadth twenty-seven. Its circumference is estimated at 140 miles. According to the statement of Mr Rickman, the extent is 837 square miles, or 535,680 acres.

The county is divided into six hundreds, or, as they are usually denominated, wapentakes; three of which are to the north and three to the south of the river Trent. It contains nine market-towns, and 207 parishes. The annual value of all the real property of the county, as taken in the year 1815, for the purposes of the property-tax, was found to be L.737,220. The number of inhabitants at each of the four decennial enumerations amounted, in 1801 to 140,350, in 1811 to 162,000, in 1821 to 186,873, and in 1831 to 225,400. The burials in the ten years from 1821 to 1831 appear to have been one in fifty-four of the inhabitants then living. The illegitimate births were one in twenty of the whole births.

The occupations of the inhabitants in 1831, according to the arranged returns of Mr Rickman, were as follow:

Occupiers of land employing labourers	2,643
Occupiers of land not employing labourers	2,414
Agricultural labourers	11,799
Employed in retail trades and handicraft	14,683
Capitalists, bankers, and professional men	2,093
Labourers not agricultural	5,628
Employed in manufactures and machinery	14,260
Other males under twenty years of age	56,582
Male servants of all ages	1,132
Female servants	7,886

The number of inhabited houses was 44,936, occupied by 47,117 families. Of these, 13,351 were employed chiefly in agriculture, 25,578 in trade, manufactures, and handicraft, and 8188 belonged to neither of the foregoing classes.

The towns and villages containing more than 1500 inhabitants, and the numbers in each, were, in 1831,

Nottingham	50,680	Lenton	3,077
Newark	9,557	Bulwell	2,611
Mansfield	9,426	Retford	2,491
Basford	6,325	Hucknal-Torkard	2,200
Worksop	5,566	Clareborough	2,106
Sutton Ashfield	4,805	Kirby Ashfield	2,032
Greasley	4,583	Carleton	1,784
Arnold	4,054	Bingham	1,738
Southwell	3,386	Stapelford	1,533

The face of the country is generally level, with moderate undulations; and its beauties are of a mild description, somewhat picturesque in the vicinity of Sherwood Forest, but displaying neither the striking features of the adjoining county of Derby on its western side, nor the flat insipidity of the plains of Lincolnshire on its eastern side. From its position between these two descriptions of country, and from its moderate elevation, it enjoys a milder climate than either, partaking neither of the raw air of the one nor the moist atmosphere of the other. The dryness of the climate is favourable to early vegetation, and is supposed to be the cause of the seed-time and harvest in Nottinghamshire commencing at the same period as in the more southern counties.

The soil of this county is very various. On the borders of Derbyshire there is a stripe of land with coal and limestone, partly in wood, but mostly under arable culture. Parallel to it is a broader tract, including Sherwood Forest, the soil of which is chiefly sandy and gravelly; but though naturally sterile, it has in some degree been brought into a productive state by the extensive cultivation of turnips, and the maintenance of considerable flocks of sheep. The tract which adjoins is a clayey soil, extending to the banks of the river Trent. It is chiefly arable land, but varied with woods and meadows, and highly productive of wheat, oats, beans, and, in some parts, of hops. The lands on the banks of the Trent are very fertile, being mostly devoted to pasture, on which many oxen are fattened; and some of the dairies are extensive. The arable land of this district is celebrated both for the quantity and the quality of the oats which it produces. The beautiful vale of Belvoir, in the south-easternmost part of the county, enjoys some of the best soils, both for pasture and arable husbandry, of any part of this island. The farms are in general small, and commonly held by tenants at will, the rents taken from whom are generally moderate; and a very great proportion of the land is free from the burden of the tithes. The spirit of agricultural improvement has not proceeded so far as in many other counties, though it has made considerable progress of late years. Neither the breeds of cows and sheep, nor the modes of cultivation, differ so much from those of the adjoining counties as to deserve any especial notice.

There are no mines except those of coal, which are exclusively confined to a narrow district bordering on Derbyshire; the coal is of good quality, very abundant, and, by means of internal navigation, diffused throughout the whole county. Excellent stone for building is raised in many parts, some of which has the peculiarly valuable quality of improving by exposure to the weather. Many parts of the county abound in veins of gypsum. In the parish of Gotham it is found in strata of the thickness of three feet. At Beaconhill, near Newark, there are large quarries of this substance. Although it has been much praised as a manure, the trials of it that have been made in its vicinity have not been attended with such beneficial results as to induce the continued use of it for that purpose.

The Forest of Sherwood, formerly celebrated as the scene of the exploits of Robin Hood, whose deeds amused our nursery days, is mostly an open heathy plain, bordered with recent plantations, and upon which the plough has made very extensive encroachments. The boundaries of the forest are extensive, it being twenty-five miles in length, and from seven to nine in breadth; but a great portion of it has become the property of private individuals, and is enclosed in farms and parks; in the latter of which is to be found the deer with which this forest was once most abundantly stocked. The trees of most ancient date are those now remaining on the estates of the Duke of Newcastle and Lord Manvers.

Nottinghamshire is, for its population, one of the greatest manufacturing counties. The frames for making hosiery were the discovery of a clergyman of this county named Lee, in the reign of Queen Elizabeth, who, finding but little encouragement in England, repaired to Paris, and commenced his work under the auspices of Henry IV. The murder of that monarch having deprived him of a patron, he died of chagrin in France, and the workmen returned home, when, after many fluctuations, the machinery was introduced into this county. The making of stockings, caps, pantaloon-pieces, and other similar articles, has long given employment to the great mass of the labouring population; and of late years the making of lace upon a similar principle has been introduced, and created additional employment. Although the riotous conduct of the workmen, under the denomination of Luddites, has driven some of the large capitalists to other parts of the kingdom, yet the hosiery business is by far the most important means of employment throughout the whole county. The spinning of cotton-yarn, from its natural connection with hosiery, has been introduced and very widely extended; and the establishments at Nottingham, at Mansfield, at Newark, at Southwell, and several other places, are upon an extensive scale. There are also several large manufactories for spinning worsted yarn. Malting and brewing are carried on to a considerable extent; and the beer of Nottingham and of Newark rivals that of Burton-upon-Trent. There are potteries at Sutton Ashfield; starch is made near Southwell; and sailcloth and candlewick at Retford.

The foreign trade of this county is mostly conducted by the mercantile houses of London and Liverpool; but some of the larger manufacturers export their own goods, both to the continent of Europe and to the more distant parts of the world.

The river Trent, the fourth in magnitude of the English streams, passes across the county, and is navigable for barges throughout the whole of it; but its deficiencies of water and its shoals are such great impediments that a canal by the side of it, ten miles in length, is found of great use to the intercourse. The other rivers are not navigable, but are beneficial for the purposes of irrigation. They are the Erwash, the Soar, the Maun, the Meden, the Wollen, the Worksop, the Idle, the Lene, and the Dover or Dare. These all discharge their waters into the Trent. The canals are, the Nottingham, the Grantham, the Idle, and the Chesterfield. The last of these is about forty miles in length; the others about ten each. By means of these and the Trent, the intercourse by internal navigation is extended to almost every district of the county.

The titles derived from this county are those of Marquis of Granby, Earl of Mansfield, Viscount Newark, and Barons Pierrepoint and Carrington. For election purposes, the county has been divided into two districts, the northern and the southern. Each of them returns two members. The election for the northern division is held at Mansfield, and the polling places are, that town, East Retford, and Nottingham. The election for the southern division is held at Newark, and the other polling places are Bingham and Southwell. The three boroughs, Nottingham, Newark, and Retford, return each two members, as before the passing of the reform bill. The whole of the county is in the diocese of York, and it is on the midland circuit of the judges.

The remains of Roman and Saxon antiquities are numerous. Amongst the former are the camps at Barton Hill, at Combes Farm, at Gringley, at Hexgrave, and at Wenny Hill, and a Roman villa near Mansfield. Amongst the latter are the Castle of Newark, the abbeys of Newstead, Rufford, and Welbeck; the priories of Mattersey and Worksop; and the churches of Bingham, Blythe, Southwell, and Balderton.

The most distinguished natives of this county have been, Archbishop Cranmer, Dr Erasmus Darwin, Sir Martin Frobisher, Denzil Lord Holles, Ireton the son-in-law of Cromwell, Lady Mary Wortley Montagu, Paul Sandby, Archbishop Secker, Gilbert Wakefield, and Bishop Warburton.

The seats of noblemen and gentlemen of the first class are as numerous as in any county of England. Of these, the most remarkable are the following, viz. Annesley Hall, J. W. Chaworth, Esq.; Babworth Hall, Honourable J. B. Simpson; Bunney Park, Lord Rancliffe; Clifton Grove, Sir Gervas Clifton; Clipstone Park, Duke of Portland; Clumber Park, Duke of Newcastle; Colwich Hall, John Musters, Esq.; Grave, A. H. Eyre, Esq.; Holme Pierrepoint, Earl Manvers; Hurgarton Hall, G. D. L. Gregory, Esq.; Kelham House, J. M. Sutton, Esq.; Langold, H. Gally Knight, Esq.; Lenton Priory, William Stretton, Esq.; Muskham, J. Pocklington, Esq.; Newstead Abbey, late Lord Byron (now the property of Major Wildman); Norwood Park, Sir Richard Sutton, Bart.; Osberton, F. F. Foljambe, Esq.; Ossington Hall, J. Denison, Esq.; Rufford Abbey, Honourable J. L. Saville; Stanford Hall, C. V. Dashwood, Esq.; Stappleford, Sir John Borlase Warren; Thoresby Park, Earl Manvers; Welbeck Abbey, Duke of Portland; Wollaton Hall, Lord Middleton; Worksop Manor, Duke of Norfolk.

NOVAIA, a small town of Tobolsk, in Asiatic Russia, situated on the Irtysch, one hundred miles east-south-east of Tobolsk.

NOVARA, a province of the duchy of Piedmont, in the continental dominions of Sardinia. It extends over 610 square miles, and comprehends one city, 117 market-towns and villages, and about 100,000 inhabitants. It is a level district, watered by the rivers Ticino, Sesia, and Agnona, the streams of which are spread by numerous small canals, so as to irrigate the whole of the surface; but as the water is not stagnant, the air is not generally insalubrious, excepting near the extensive rice-grounds. Much corn is raised, and some of the best silk, with hemp, flax, and fruits.

The capital is the city of the same name, situated on a

Nova Scotia.

hill at the foot of which flows the river Agnona; it is fortified, is the seat of a bishop, and has a cathedral. It contains several parish churches, seventeen convents for the two sexes, and two thousand houses, with 14,662 inhabitants. The city has two colleges and a theological seminary. The chief occupations of the inhabitants consist in weaving silk and linen, and some smaller trades. Long. 8. 32. 25. E. Lat. 45. 26. 58. N.

NOVA SCOTIA, a British province of North America, situated between the parallels of 43. 25. and 46. 0. north latitude, and the meridians 61. 0. and 66. 30. of west longitude, and connected with the south-east part of the continent by an isthmus of only eight miles in width. It is bounded on the north by the Strait of Northumberland, which divides it from Prince Edward Island; on the north-east by the Gut of Canseau, which interposes between it and the island of Cape Breton; on the south and south-east by the Atlantic Ocean; on the west by the Bay of Fundy; and on the north-west by New Brunswick. Its extreme length from Cape Canseau on the east to Cape St Mary's on the west is about 280 miles; but its breadth varies from fifty to about 100 miles, and it contains a superficies of about 16,000 square miles, or upwards of nine millions of acres. From this, however, nearly one third may be deducted for lakes, arms of the sea, and rivers, leaving about seven millions of acres of land, five millions of which may be considered as adapted for cultivation, and the remainder as affording tolerable pasturage. It is estimated that above three millions of acres of these lands still remain vacant, and in the hands of the crown; but the largest unoccupied tracts do not in one place exceed forty thousand acres.

The most remarkable physical characteristic of this peninsula of the North American continent is the numerous indentations along the coast. The shores are lined with rocks, and studded with thousands of small islands; and close to these, and in the harbours, almost without exception, there is a considerable depth of water. All along the southern shore there is a succession of noble harbours; and coasting vessels sail amongst and within the myriads of islands which line the coast during the most blustering weather, thus enjoying comparatively smooth water, whilst the main ocean heaves in violent agitation. The interior of the country is very agreeably diversified with hill and dale, river and lake, forest and grassy plain. The surface, although undulating, is not mountainous, the highest land, Ardoise Hill or Arthur's Seat, being only 810 feet above the level of the sea, nearly the same height as Arthur's Seat at Edinburgh. The highlands generally run north and south, branching off in all directions, and in some instances terminating in bold cliffs on the coast, the most remarkable of which is Aspotagoen, between Mahon and Margaret's Bay, which is about 500 feet in height. The Horton Mountains run nearly north and south; and the north mountains, which are washed by the Minas Basin, terminate in Cape Blomidon. The Blue Mountains, which lie in the interior of the counties of Annapolis, Shelburn, and Queen's, are said to retain traces of volcanic eruption. There is a great variety of rocks in Nova Scotia, but granite, trap, and clay-slate predominate. The most abundant variety is the gray granite, which prevails along the shore, and is well adapted for mill-stones. Trap rocks, sometimes interstratified with clay-slate, protrude in various places in immense parallel ridges above the surface, and frequently in piles of loose masses heaped confusedly together, traversed frequently by veins of quartz. Clay-slate of a very fine quality, and used as a building stone, prevails in the eastern section of the colony; and graywacke and graywacke-slate extend along both shores of Chedabucto Bay, in which are found beds of limestone and numerous species of specular iron ore. In connection with carboniferous limestone are found, both in Cape Breton and Nova Scotia, those immense coal fields which are supposed to rival in extent the mines of the mother country. Varieties of copper, iron, and lead ores are also abundant; and different other minerals of less importance are found. Salt springs, some of them strongly impregnated with saline matters, are met with near Pictou, at River Philip, and some other parts. The soil of Nova Scotia is of many different qualities, and various degrees of fertility. The alluvial, or intervale lands, of which there are extensive tracts, are rich, and produce plentiful returns of wheat, barley, oats, Indian corn, potatoes, turnips, with all the vegetables and fruits common in England. Some of the uplands, lying between the hilly country and the rivers, are light and poor, whilst the high lands are rich and very productive. The lands on the southern coast are generally so rocky as to admit of cultivation only at much expense and labour; but after the stones are removed, the soil is by no means barren.

The interior of Nova Scotia is intersected and watered by numerous rivers, lakes, and streams, which beautify and enrich the country. The two largest rivers are the Annapolis and the Shubneccadie. The former takes its rise in King's county, and, running parallel with the bay of Fundy, after a long and serpentine course, in which it receives the Moose and Bear Rivers, discharges itself into Annapolis Bay. It is navigable to a considerable extent, and its banks present a rich and pleasing landscape. The Shubneccadie, issuing from the Grand Lake in the county of Halifax, divides that county from Hants, and, after a rapid and circuitous course, the length of which has not yet been accurately ascertained, discharges itself into the Bay of Minas. It receives the waters of ten other rivers, is navigable for large vessels a long way into the interior, and contains on its banks inexhaustible quantities of gypsum and lime, together with extensive groves of fine timber. At Pictou, three rivers, navigable for large vessels, empty themselves into the harbour; the East, West, and Middle Rivers. Besides these, there are the Avon, navigable for a considerable distance; the La Have, which issues from a chain of interior lakes, and has a course of about sixty miles; the Mersey, which winds from Lake Rosignol through the Queen's county, and discharges itself into Liverpool Harbour; the Medway, the Shelburn, the Clyde, the Tusket, the St Mary, and others, all of which owe their origin to lakes in the interior. The most extensive still sheet of water is the Rosignol, situated partly in each of the three counties of Queen, Shelburn, and Annapolis. It is said to be thirty miles in length, but is little known. Lake George is also of considerable size; and there are innumerable others, which it is unnecessary to mention. The forests of Nova Scotia still constitute a prominent feature of the country. The trees are the same as those common to America, and the timber is generally large and lofty. Amongst the natural curiosities of this country is a huge granite stone, supposed to weigh about a hundred and sixty-four tons. It stands on the margin of a small lake, encircled with wood, near Halifax, and is so nicely poised on a flinty base of twelve inches, that the strength of one hand will put it in motion, but that of several hundreds could not shift it from its place. There are several remarkable caverns and grottoes, one of which, at St Peter's Point, on the coast of the Bay of Fundy, displays in the interior a spacious hall, the roof of which is fretted with stalactites; and brilliant gems are observed sparkling at the moment that the light of a torch or a candle approaches. The climate of Nova Scotia was for many years after its discovery considered as an insuperable barrier to agricultural industry, and an idea long prevailed in England that it was peculiarly the region of snow and fog. The temperature is indeed colder in winter in this peninsula than it is in Great Britain;

but when the weather is cold it is usually dry, and altogether the winter is milder, and the summer less intensely hot, than at Quebec. The summer heat is moderate and regular; the autumn is a delightful season; and there is seldom any severe winter weather until the end of December. Frost continues generally from Christmas to April, only interrupted by a thaw, which almost invariably takes place in January. The heaviest snow-storms occur in February. Rain falls in greatest abundance in spring and autumn; and a fog prevails on the south shore near the mouth of the Bay of Fundy, but does not extend far inland.

The wild animals are the moose, carriboo, bear, loup-cervier, tiger-cat, fox, marten, otter, mink, beaver, musk-rat, porcupine, racoon, wood-chuck, fisher, weasel, squirrel, hare, and the like, all of which, excepting the two last, have rapidly decreased in number. Nearly all the birds common to North America frequent Nova Scotia; and there are but very few kinds of fish which are found in the American seas that do not frequent the shores of this colony in vast swarms.

Nova Scotia is divided into ten counties, including Cape Breton; and the counties are subdivided into districts and townships as follows, viz. Halifax, divided into the districts of Halifax, Colchester, and Pictou, and containing the townships of Halifax, Dartmouth, Preston, Lawrence Town, Truro, Onslow, Londonderry, Pictou, Egerton, and Maxwelton; Lunenburg, containing the townships of Chester, Lunenburg, and Dublin; Queen's county, containing the township of Liverpool; Shelburn, containing the townships of Shelburn, Yarmouth, Barrington, Argyle, and Pubnico; Annapolis, containing the townships of Digby, Clements, Clare, Annapolis, Granville, and Wilmot; King's county, containing the townships of Aylesworth, Cornwallis, Horton, and Sherbrooke; Cumberland, containing the townships of Wallace, Amherst, and Pamborough; Hants, containing the townships of Falmouth, Windsor, Rawdon, Kempt, Douglas, and Newport; Sydney, divided into the Upper and Lower Districts, and containing the townships of St Mary's, Guysborough, Manchester, Wilmot, and Dorchester, or Antigonish; and Cape Breton, divided into the north-western, north-eastern, and southern districts. The townships are not all of equal extent, nor are there, as will be seen, the same number in each county. The inhabitants meet, like an English parish, in vestry, and assess themselves for the support of the poor. This regular subdivision affords facilities for the administration of justice; and the principal townships send representatives to the House of Assembly.

Halifax is the largest county in the province, stretching quite across it from the Atlantic Ocean to Cumberland Straits. It is bounded on the east by the county of Sydney, on the west by the counties of Hants and Lunenburg, and on the north by the county of Cumberland. The whole southern shore is washed by the Atlantic Ocean, and a part of the northern shore by Northumberland Straits. With the exception of the township of Halifax itself, the general appearance of the three districts into which the county is divided corresponds with that of the province as a whole; its surface being everywhere diversified by hill and dale, and well irrigated by rivers and brooks. All the southern part which lies upon the Atlantic is high, broken, rocky land, interspersed here and there with some good belts of soil, but in general it is barren and uncultivated. The extensive tract of country surrounding the Great Lake bears the same character, as does that which extends several miles along the eastern and western sides of the Shubneccadie River. Halifax, the capital city of the province, is situated on the south-east coast, in latitude 44. 40. north, and longitude 63. 40. west. It is built on the eastern side of a small peninsula, upon the declivity of a hill, which rises gradually from the water's edge; its length being about two miles, and its breadth about half a mile, with wide streets crossing each other at right angles, and containing nearly 2000 houses, and a population, including strangers, of about 20,000. It has been very much improved within the last ten years. The front of the town is lined with wharfs, alongside of which vessels of all sizes are continually discharging or taking on board their cargoes. The harbour of Halifax has perhaps not a superior in any part of the world, affording safe anchorage for a thousand ships at once; and it is accordingly the chief naval station of Great Britain in North America. It is accessible at all seasons of the year, being scarcely ever ice-bound, as Quebec annually is. It lies nearly north and south, extending in this direction about sixteen miles, and terminating in a beautiful sheet of water called Bedford Basin, within which are ten square miles of excellent anchorage. The bay from which the entrance of the harbour leads is formed between Sambro Head and Devil's Island, on the former of which a lighthouse was very early erected. There are four islands still farther in, upon the smallest of which, opposite the town, there are batteries strongly mounted, whilst several other fortifications command the harbour. A second lighthouse has been established on M'Nab's Island, situated near the mouth of the harbour. This island forms two entrances to the harbour; the eastern passage being for small vessels only, the other having depth of water for ships of all sizes. Above the wharfs already mentioned are numerous warehouses; and on the acclivity are the houses of the citizens, public buildings, and other structures. The houses are very irregular in height, but many of them are handsome stone and brick buildings, whilst those of wood are neatly faced with plaster or stucco. The public edifices are substantial, the Province Building in particular being one of the finest in our American colonies. It contains chambers for the council and legislative assembly, the supreme court, and all the provincial offices. The government-house, at the south end of the capital, is an antique baronial-looking edifice; and the military hospital, and other structures, are elegant and substantial. The dock-yard is one of the finest establishments out of Britain. There are a number of churches, and other places for public worship; and several markets, which are extremely well supplied with necessaries. Amongst the benevolent institutions of this city may be mentioned a college, which was established in 1820; and seven or eight newspapers, and a monthly magazine, are published. The intercourse between Halifax and Europe, America, the West Indies, &c. is regular and certain; and ever since its first settlement in 1749, it has continued to be of considerable importance, not only as a rendezvous for his majesty's ships, and as the head-quarters of the troops on the establishment of the lower American provinces, but also as the centre of a profitable fishery and trade. The manufactures carried on consist chiefly of sugar-refining, distillation of spirits, porter and ale brewing, and the making of soap, candles, leather, flour, and cordage, and a few other minor articles. Halifax is a free warehousing port, and its trade is very considerable.

Opposite to Halifax, on the eastern side of the harbour, stands the little town of Dartmouth. It was laid out about the time that the capital was founded, but in 1756 it was destroyed by the Indians, together with most of the inhabitants. It was subsequently resettled, and has slowly increased in population, and extended in size. The lands on the Dartmouth side of the harbour are much less stubborn than those on the opposite shore; and the industrious descendants of the original German settlers have long subjected them to a fair and profitable cultivation. The various other townships or settlements in the county of Halifax it is unnecessary to particularize individually.

Nova Scotia.

They all contain a considerable quantity of excellent soil, and a small town or hamlet where the settlers reside. Truro, situated on the southern side of Cobequid Bay, near its head, contains about one hundred houses, and a number of public buildings. The district of Pictou, which contains three townships, has a very good soil, and, besides a great coal-field, abounds with iron ore, copper, freestone, and lime. It has a number of excellent harbours, the principal port being called Pictou. It is admirably situated on the Straits of Northumberland, opposite Prince Edward Island, on the route from Halifax to Quebec, between which places there is not a safer or better shelter for ships. The town of Pictou, situated about two miles from the entrance, is well built, and contains four churches, with other public edifices, and about 3000 inhabitants. It is a free port, and its trade in lumber, coal, and the fishery, is considerable. An excellent newspaper is published at this place.

The county of Lunenburg is bounded on the north by King's county and that of Annapolis, on the south by the Atlantic Ocean, on the east by Halifax, and on the west by Queen's county. It extends forty miles from east to west, and its extreme width is thirty-five miles, exclusive of nearly three hundred islands scattered along its shores. The land is in general covered with spruce and fir timber, well watered, and capable of cultivation. The principal harbour is Mahon Bay, which is very extensive, and affords secure anchorage inside its numerous islands to vessels of the greatest magnitude. Chester town is situated on the north side of the bay, about nine miles from its mouth, upon a snug and commodious harbour. It is a thriving place, and carries on a very considerable lumber trade and fishery. It was first settled by people from New England, who afterwards abandoned the place. They were succeeded by Germans, who, being industrious, soon secured their own independence and the prosperity of the settlement. The population of the bay amounts to about 2000, who are chiefly employed in agriculture, preparing lumber for exportation at the saw-mills, and in fishery. Near the entrance of Mahon Bay, upon the western side, lies the harbour of Lunenburg, the county town. It is regularly constructed, and contains the county buildings, above 140 dwelling-houses, besides stores, and about 1400 inhabitants of Dutch and German origin. A few miles to the westward is La Have, one of the largest rivers in Nova Scotia, and settled principally by Germans, who own a number of saw-mills and grist-mills. The harbour is very spacious, consisting of an outer and an inner place of anchorage. Considerable quantities of fish are taken here, and several vessels are annually freighted with lumber and timber for Great Britain. Several islands well calculated for drying fish lie at the entrance, and they also form a protection to the shipping. Most of the islands in this county remain in their natural state; but one, called the Great Tancook, is settled, and contains thirty families.

Queen's county is bounded on the east by the county of Lunenburg, on the west by the county of Shelburn, on the north by the county of Annapolis, and on the south by the Atlantic Ocean. The interior of this county is stony, and generally incapable of cultivation. On the sea-board, however, it is better, and there are here several tracts of respectable soil, and some thriving settlements. Liverpool, the county town, and the second place in the province, is situated upon a harbour of the same name, about eighty miles west from Halifax. It is regularly laid out and well built, containing a court-house, jail, several places of public worship, a fort, above two hundred dwelling-houses, and a great many wharfs, stores, and other buildings. There is a good lighthouse at the entrance of the harbour, which never freezes over. The trade of the place is very flourishing, consisting chiefly in lumber and fish; but a considerable trade in timber is also carried on. Port Medway, into which the river Medway runs, is a very fine harbour, capacious, and safe. There are some other small settlements in this county, but none requiring special notice.

Shelburn county is bounded on the north by Annapolis county, on the south and west by the Atlantic Ocean, and on the east by Queen's county. It contains four townships, one of which, Yarmouth, comprises 100,000 acres of land, exclusive of lakes, of which Lake George is one. In the interior, this county remains, with few exceptions, in the state of a wilderness; but some parts are agreeably diversified, and in point of scenery it is one of the most beautiful portions of Nova Scotia. Shelburn, the shire-town, is built upon a harbour of the same name, which is esteemed one of the best in America. It has a lighthouse at the entrance, and is twelve miles in length, easy of access, and perfectly secure, affording anchorage for the largest vessels. This town was at one time of considerable importance, containing, it is said, about 12,000 inhabitants; but the population does not now exceed 500. A few miles westward of Shelburn is Cape Negro Harbour, sheltered by a high island of the same name. It forms the embouchure of the river Clyde, which winds forty miles through the county, has finely wooded banks, and, next to Annapolis, the most beautiful stream in the province. Within Cape Sable Island, the most northern point in Nova Scotia, is Barrington Harbour, where fishing to a considerable extent is carried on. Yarmouth or Cape Fourché Harbour is the principal and most thriving place in this part of the province. Its harbour is large, well sheltered, safe, and navigable for ships up to Yarmouth village. Yarmouth and its neighbourhood contain an industrious population of about 4500 inhabitants, who possess about seventy vessels and large stocks of cattle. It has always gone on steadily improving, and promises, from its numerous local advantages, to become a place of considerable importance. Shebogue River, in this part of the province, is navigable for seven miles from the sea, and at its mouth expands into a good harbour.

Annapolis county is bounded on the north and west by the Bay of Fundy, on the south by Shelburn, Queen's, and Lunenburg counties, and on the east by King's county. The first European settlements in Nova Scotia were established in this county by the French, who made some very extensive improvements. They founded Annapolis, the county town, and gave it the name of Port Royal. It is built upon a peninsula, which, projecting into the river of the same designation, forms two beautiful basins, one above and another below the town. Although once the metropolis of Nova Scotia, it is not now more than a thriving village, containing about sixty dwelling-houses, with the government buildings, several places of public worship, and some stores. The trade is comparatively insignificant, and arises principally from the fishery. Digby, which has sprung up into a town within the last fifty or sixty years, is a much larger place, containing about two hundred houses. The inhabitants here and in the neighbourhood are principally engaged in the cod and mackerel fishery along the coast. Bridgetown, another thriving village, is situated at the head of the navigation of the river, and from this place the produce of the inland districts is shipped for exportation. Fish of various kinds, such as shad, bass, salmon, and particularly herring frequent Annapolis basin. About seven miles from Annapolis, on a stream called Moose River, an iron foundery has been established by a company under the protection of a legislative charter. The buildings are extensive and substantial, and the iron ore is excellent; but a similar work at Pictou possesses the great advantage of a coal mine in the immediate vicinity. The basin of Minas, in this county, is one of the two great

Nova Scotia.

branches of the Bay of Fundy. Its entrance is through a strait about three miles in width, with bold, abrupt shores, within which it widens from eight to sixteen miles, and, receiving the waters of upwards of twenty rivers and streams, extends about fifty miles to the head of Cobequid Bay. The tide rises sometimes so high as seventy feet in the bay, and flows with great rapidity, particularly when under the influence of high winds. The other townships of this county are thriving places, containing from 1000 to between 3000 and 4000 inhabitants.

King's county is bounded on the south by the counties of Lunenburg and Hants, on the north by the Bay of Fundy, on the east by Cumberland county, and on the west by that of Annapolis. The township of Horton, in this county, contains about 4000 acres of diked land, besides intervale and salt marshes; and the upland, which is hilly and broken, consists mostly of good tillage land. The principal town is Kentville, on the borders of Cornwallis, containing several good private houses, a court-house, a jail, and a grammar school. The township of Cornwallis is well watered by several rivers, and the land throughout is of the very best quality, being so fertile as to have obtained the name of the garden of the province. The township of Aylesford is similar to it in soil and productions; but that of Parrsburgh is much broken and hilly, although in many parts the soil is excellent.

Cumberland county is bounded on the north-west by the Chignecto Channel, the Missiguash River, and part of New Brunswick; on the east by the straits of Northumberland; on the south-east by the county of Halifax; and on the south-west by King's county. The soil of this county is various, containing a considerable portion of excellent land, with some that is not so productive. On the shore of the Chignecto Channel and Cumberland Basin there are considerable tracts of valuable marsh land. The upland is in general of very superior quality, and there are several thousand acres of dike land of the most productive description. Coal, lime, and gypsum, are found almost everywhere; and iron and copper ores have been discovered at several places. Rivers and streams traverse the county in almost every direction, and it has several fine harbours on both its shores. It contains a number of thriving settlements, particularly those of Fort Lawrence, Amherst, Wallace, and West Chester; but none of the towns requires particular notice.

Hants county is bounded upon the north by the Minas Basin, on the east by Shubneccadie River, which separates it from Halifax, on the south by parts of the counties of Halifax and Lunenburg, and on the west by King's county. This county contains a considerable quantity of the very finest soil, and is well settled throughout. Windsor, the shire-town, is situated at the confluence of the Avon, Windsor, and St Croix Rivers, and is a neat, well-built place, containing about one hundred and thirty dwelling-houses, and a number of public buildings, particularly an university, King's College, an academy called the Collegiate School, and several places of worship. This is the only town in the county, the other settlements being small hamlets planted in positions favourable for agriculture or fishing.

Sydney county, forming the most easterly part of the province, is bounded on the west by the county of Halifax; on the south by the Atlantic Ocean; on the east by Chedabucto Bay, the Gut of Canseau, and St George's Bay; and on the north by Northumberland Straits. It is divided into an upper and a lower district, the former being, in an agricultural point of view, far superior to the latter; and, notwithstanding the numerous and beautiful harbours on the bays and coasts, and the valuable fisheries, it is much more populous. The village of Dorchester, situated about a mile above the navigation on Antigonish River, is the principal trading place in the district. The lower district of Sydney extends on its interior or northern boundary about forty miles, and on its western side (on the sea coast) about one hundred and twenty miles. No part of Nova Scotia, and perhaps few countries in the world, can boast of so many excellent harbours in the same extent of coast. Many of them are navigable for the largest vessels, and numbers affording safe and extensive anchorage-ground for ships of moderate size occur at intervals of only a few miles. The soil along the shore being stubborn, the agricultural resources of this part of the county are inferior to those of the upper district; but it possesses much greater facilities for commerce and navigation, and its fisheries are the best in the province.

For a general description and history of Cape Breton, the reader is referred to the article Breton, Cape. In many respects it bears so close a resemblance to Nova Scotia as to supersede any further description. The staple products of the island are fish, coal, gypsum, and timber. In 1832 the exports were, timber, 9500 loads; coals, 22,911 chaldrons; pickled fish, 21,000 barrels;[1] dried fish, 44,000 quintals; oil, 2500 barrels; live stock, 820 head; oats, 6000 bushels; potatoes, 13,000 ditto; total value, L.780,000. The imports, consisting chiefly of British manufactures, amount to nearly the same sum. The revenue, amounting to about L.4000 a year, is expended in salaries to a few public functionaries, in improving roads, and for other purposes. This island is incorporated with Nova Scotia, and contains about 30,000 inhabitants, who send two members to the Provincial Assembly.

Sable Island, although distant about eighty-five miles from Nova Scotia, is considered as belonging to that province. It lies directly in the track of vessels bound to or from Europe, and has been the scene of numerous and melancholy shipwrecks. Within a few years forty vessels have been wrecked on it; and in one year two hundred people perished on its shores. It is thirty miles in length by about one and a half in breadth, the west end being in latitude 43. 56. 42. north, and longitude 60. 71. 15. west; and the eastern end in latitude 43. 59. 5. north, and longitude 59. 42. west. It is a barren desert throughout, the soil consisting chiefly of sand, and the only vegetable productions being a coarse grass and some wild berries. A sum of L.800 is devoted to keeping on the island a superintendent from Nova Scotia, with a party of men provided with provisions and other necessaries, for the purpose of affording assistance to any shipwrecked mariners, of whatsoever nation, who may be driven upon its inhospitable shores. There is a small stock of cattle on the island, but the chief supplies of food are obtained from Nova Scotia.

Agriculture was long almost entirely neglected in Nova Scotia, as other pursuits afforded a more immediate return for labour and capital. In fact, the cultivation of the soil was looked upon as rather a degrading employment, and ranked far below that of the petty shop-keeper or itinerant pedlar. In 1817, however, a board of agriculture was formed, the objects of which were, the encouragement of agriculture on the most approved system; the improving of the breed of horses, and of all kinds of live stock; the importing of the best kinds of seeds, and the awarding of prizes to those who should excel in these various departments. Under the auspices of this society and its numerous branches, agriculture has made greater advances than could have been anticipated from the contempt in which it had previously been held; but still farming operations are rather clumsily conducted.

[1] A great part of the fish taken here is transported directly to Halifax, and therefore does not appear in the Cape Breton returns.

Nova Scotia.

The soil will produce, and the climate ripen, all the agricultural productions of England in great perfection, so that it is unnecessary to specify individual crops. The province is well stocked with horses, horned cattle, sheep, and swine; and the last species of stock has more than doubled within the last twenty-five years. There are few manufactures, properly so called, carried on in Nova Scotia; but the preparation of lumber and ship-building are sometimes so denominated. Saw-mills abound in every district, and the quantity of lumber prepared and exported is immense. Ship-building is carried on to a great extent. The average quantity has been estimated at 10,000 tons per annum, principally sloops, schooners, and vessels for the fisheries. The total quantity of timber shipped from the colony in 1833 was valued at L.62,447. The total value of the produce of the mines exported was L.105,329, and of the fisheries L.127,455. There were exported besides, beef, pork, flour, grindstones, gypsum, and other articles, to the value of L.592,136, making the total amount of exports L.887,367. The following parliamentary return presents a tabular view of the exports from Nova Scotia, exclusive of Cape Breton, for several years ending 5th January.

	1830.	1831.	1832.	1833.	1834.	
Seal skins	14,913	3,365	49,412	51,918	22,229	number.
Oil	618	715	694	704	596	tons.
Fish, dry	158,289	151,807	161,174	160,640	232,269	quintals.
Ditto, pickled	45,741	45,433	52,063	36,070	53,128	barrels.
Ditto, ditto	3,416	2,999	3,200	2,168	1,470	half ditto.
Timber, &c.	25,182	26,182	33,261	38,192	36,386	tons.
Gypsum	28,059	44,253	47,857	45,058	93,962	ditto.
Boards and planks	12,450,250	9,876	8,833	9,984	14,774	feet.
Vegetables	68,213	63,503	58,691	64,712	75,592	bushels.
Spars	976	1,322	689	1,689	2,366	number.
Staves	4,068	3,051	2,386	2,714	3,133	thousands.
Grindstones	...	...	...	2,192	36,386	tons.

The fish is thus the staple article of the trade of this province. The fishery is carried on principally on the eastern shore, in and about Chedabucto Bay; on the southern shore, at Lunenburg, Liverpool, and Shelburn; on the western shore, at Yarmouth, Clare, Argyle, and Barrington; and at Annapolis, in the Bay of Fundy. The fish principally taken are cod, herrings, mackerel, shad, alewives, and salmon. The British fishermen complain much of the injuries which they receive from the French and Americans, who are permitted to fish upon the coasts of our North American colonies.

The imports of Nova Scotia consist chiefly of British manufactures and spirits, sugar, wines, and other articles from our colonies. The following is an abstract of goods imported between the 31st of December 1832, and the 31st of December 1833, for which duties were paid or secured at the excise office, including the island of Cape Breton:—Wine, 113,671 gallons; rum, brandy, and gin, 887,352 gallons; sugar, 41,990 cwts.; beef and pork, 6016 pounds; flour, 32,263 pounds; tobacco, 186,690 pounds. The amount of goods imported, paying *ad valorem* duties, was L.347,388, and the amount of duties levied was L.105,386. The total value of the importations for that year was L.1,035,660.

With regard to the shipping of the colony, the total number of vessels inwards in 1833 was 1950, of 163,385 tons; and in 1834, 3068, of 253,921 tons. The total number outwards in 1833 was 2330, of 179,956; and in 1834, 3116, of 250,239 tons. They belonged chiefly to Great Britain and the British colonies. To show the increase of trade, it may be stated, that in 1807 the shipping entering Nova Scotia was not more than 25,000 tons.

The revenue of Nova Scotia is chiefly derived from the custom and excise duties above mentioned, to which are added other items of small amount derived from the sale of crown lands, which in 1831 realized L.645, and in 1832, L.1063; from the rent of the coal-mines, which is upwards of L.4000 per annum; and from the lighthouse dues, which amount to an annual average of L.2000. According to a document first printed in Mr Montgomery Martin's work on the British colonies, the revenues for a series of years were as follow:—

Years.	Colonial Gross Revenue.	Parliamentary Grants.	Total.
	£	£	£
1821	31,430	...	31,430
1822	32,097	...	32,097
1825	37,004	9,395	46,399
1826	38,360	11,245	49,605
1827	59,886	...	59,886
1829	81,887	13,998	95,885
1830	52,030	16,245	68,275
1831	85,018	13,125	98,143

The colony of Nova Scotia is quite adequate to defray all its civil expenditure, and the parliamentary grants, much of which had been applied to clerical purposes, were nearly all withdrawn in 1833, with the exception of that given to the Society for the Propagation of the Gospel. In 1831 the civil and military expenditure amounted to L.94,876, which was less than the revenue. Besides the salaries of the different functionaries, a considerable sum has been laid out annually in making and repairing roads and bridges, keeping up lighthouses, and for the purposes of religion and education. The established church is Episcopalian, and under the management of a bishop, archdeacon, and thirty-two clergymen, who by the last census had under their charge 28,659 people. Of the church of Scotland there are twelve ministers, having 37,227 hearers. Of the Roman Catholic church there are a bishop and fourteen priests, with 20,401 members. There are, besides, 19,790 Baptists, 9408 Methodists, 2968 Lutherans, 4417 dissenters from the church of England, 405 from the church of Scotland, 153 Quakers, and some few other persuasions. About 50,000 acres of land have been granted for the support of religion and schools. For the year ending November 1832 there were in the province 420 schools, at which 11,771 scholars attended; and independently of these there were twenty-four grammar-schools. Dalhousie College, at Halifax, is in constitution similar to the University of Edinburgh. There is a fine institution, called King's College, at Windsor, with regularly educated professors and others; and Pictou College is likewise an excellent institution.

Nova Scotia is governed by a lieutenant-governor, council, and house of assembly. The president of the council is the chief justice of the province; the next in station is the bishop, and there are ten other members. The house of assembly contains forty-two members, each of the ten counties returning two, except the county of Halifax, which returns four, and the town of Halifax two; seventeen other towns return each a member, and the island of Cape Breton sends two. The house of assembly act, and the laws are administered, as in Canada. There is a strong body of militia for the defence of the province, the name of every male from sixteen to sixty being enrolled. The king's troops consist of artillery and engineer detachments, and two regiments of infantry. Halifax is the chief naval station for the West Indies and North America, the commander-in-chief being a vice-admiral, with a suitable fleet. The forts protecting Halifax town and harbour are strong, and the interior of the country is well guarded by the militia.

By the last census, which was taken in the year 1827, the population, exclusive of Cape Breton, was 123,848. In 1837 it cannot be estimated under 145,000; for during the last ten years a great quantity of land has been sold, and a number of settlers have gone out, whilst the revenue has also greatly increased. The inhabitants consist of natives, the descendants of Europeans, English, Scotch, Irish, Americans, loyalists, Germans, Acadian French, Indians, and freed negroes. They mingle and live together in much harmony, and, generally, the social state of this province is rapidly improving. Its prosperity has greatly increased; and, instead of importing, it now exports provisions. Its fisheries, to which proper attention is at length paid, its rich and prolific soil, and its mines of coal and iron, are sources of wealth which were too long neglected by Great Britain.

Our limits will only admit of a brief abstract of the history of Nova Scotia. Ancient authorities state that it was discovered by the Cabots in 1497; but it was not until 1604 that the French attempted to form settlements. They were, however, expelled from it by the English colonists of Virginia, who claimed the country in right of the discovery of Sebastian Cabot. In 1621, Sir William Alexander obtained a grant of the whole peninsula, and it was named in the patent Nova Scotia, instead of Acadia, as the country was called by the French. In the mean time, the latter obtained a footing in it a second time; and it was not until 1654, when a strong force was despatched by Cromwell, that the French settlers were brought under subjection. In 1667, Nova Scotia was ceded to France by the treaty of Breda; but, after suffering during the war which broke out in 1701, as well as previously, it was finally ceded to England by treaty in the year 1711. From this period till 1749 it was neglected by Great Britain; but the designs of the French called the attention of government to the province. Encouragements were held out to settlers, parliament gave a large grant, and about 4000 adventurers with their families embarked for the colony. Halifax was immediately founded; but the French settlers, under the name of neutrals, were still very numerous; and, with the aid of the Indians, they inflicted repeated injuries upon the British, until they were forcibly expelled by the latter. In 1758 a constitution was granted to Nova Scotia; and the capture of Louisburg, in the island of Cape Breton, during the same year, gave additional security to the colony, which now began to improve. By the treaty of Paris, 10th of February 1762, France resigned all further claims on any of her former possessions in North America, and nothing of any material importance has since occurred. New Brunswick and Cape Breton were separated into two distinct governments in 1784, and the latter was re-annexed to Nova Scotia in 1819. This the colonists strongly protested against, and applied to government to allow them to remain as a separate province; but, as might have been expected, their application proved unsuccessful. (R. R. R.)

Novatian || Novation.

NOVATIAN, a priest of Rome, but originally a pagan philosopher. He was baptized in bed when dangerously ill; having recovered, he was afterwards ordained priest through the favour of his bishop, although the clergy and the people were far from being disposed to grant it. He does not appear to have had the good of the church much at heart; for, with his wit, knowledge, and eloquence, he might have been peculiarly serviceable to her, had he not meanly shrunk from his duty when he dreaded persecution. His ambition to be a bishop likewise misled him; and the circumstance which occasioned the apostacy of most of the first heresiarchs also occasioned his. On the death of Fabian, bishop of Rome, Novatian, after writing a letter to St Cyprian, remained quiet whilst the see was vacant; but the promotion of Cornelius excited his envy and jealousy to the highest pitch. The consequence was a separation from the new bishop, and from those who professed to believe, what Novatian strenuously denied, that the church could receive those again who had been guilty of idolatry. He soon got together a number of followers amongst the laity, and some even amongst the clergy. Novatus, a priest of Carthage, was one of his party, and having been opposed to St Cyprian, brought his adherents with him. In an infamous and clandestine manner he got himself consecrated bishop of Rome, by three weak men, whom he had grossly imposed upon; and one of them afterwards did penance for having been concerned in what was so contrary to order, decency, and the rules of the church. His designs, however, in this disgraceful affair did not succeed; for he was not acknowledged as bishop of that diocese, Cornelius being confirmed in it, whilst he was condemned and excommunicated. He still, however, taught his doctrine, and at length became the head of the party which bears his name. St Jerome says he wrote on the Passover, on the Sabbath, on Circumcision, on the high priests, on prayer, on Jewish meals, and on firmness of mind, besides a large treatise on the Trinity. But none of these works appears under his own name, and some are thought not to be his.

NOVATIANS, *Novatiani*, a sect of ancient heretics, who arose towards the close of the third century, and were so called from Novatian, a priest of Rome. They were also denominated *Cathari* or Puritans. Novatian first separated from the communion of Pope Cornelius, on pretence of his being too easy in admitting to repentance those who had fallen off in times of persecution. Novatus coming to Rome, joined himself to the faction of Novatian, and both maintained that there was no other admission into the church but by the repentance in baptism, grounding their opinion on the words of St Paul: "It is impossible for those once enlightened, and who have tasted the heavenly gift, if they fall away, to renew themselves by repentance." Not that they denied but a person who had fallen into any sin, however grievous, might obtain pardon by repentance; for the Novatians themselves recommended repentance in the strongest terms. But their doctrine was, that the church had not the power to receive sinners into its communion, as having no way of remitting sins but by baptism, which, once received, could not be repeated. In process of time the Novatians softened and moderated the rigour of their master's doctrine, and only refused absolution to very great sinners. The two leaders were proscribed, and declared heretics, not for excluding penitents from communion, but for denying that the church had a power of remitting sins.

NOVATION, or INNOVATION, in the *Civil Law*, denotes the change of one kind of obligation for another; as when a promise is accepted instead of a written obligation.

NOVATUS, a priest of Carthage in the third century, who, to avoid being punished for a crime, joined with the deacon named Felicissimus against St Cyprian. In 251 he went to Rome, and there found Novatian, who had acquired great reputation by his eloquence, but who murmured at his not being raised to the see of Rome in preference to Cornelius. Novatus soon contracted a friendship with him, and afterwards promoted the consecration of Novatian. This irregular proceeding produced a very great schism. Novatus also maintained that the church had not the power to receive those into communion who had fallen into idolatry.

NOVEL, a fictitious narrative in prose, which professes to exhibit the natural workings of the human heart, the happiness and misery of private life, and, above all, the nature of the affection called love, and the consequences of indulging it in certain circumstances. A critic, by no means too indulgent to works of fancy, and amongst whose failings laxity of morals has never been numbered, thus expresses himself on the subject of novel-writing. "These familiar histories," says Dr Johnson, "may perhaps be made of greater use than the solemnities of professed morality, and convey the knowledge of vice and virtue with more efficacy than axioms and definitions. But if the power of example is so great as to take possession of the memory by a kind of violence, and produce effects almost without the intervention of the will, care ought to be taken, that, when the choice is unrestrained, the best examples only should be exhibited; and that what is likely to operate so strongly, should not be mischievous or uncertain in its effects."

We have said that the novel professes above all things to exhibit the nature of love, and its consequences. Whether this be essential to such performances, may perhaps be reasonably questioned; but it has been made an important part of the drama in most novels, and, we think, with great propriety. It is the object of the novellist to give a true picture of life, diversified only by accidents that daily happen in the world, and influenced by passions and qualities which are really to be found in conversing with mankind. To accomplish this object, he conceives a hero or heroine, whom he places in a certain rank of life, endows with certain qualities of body and mind, and conducts, through many vicissitudes of fortune, either to the summit of happiness or to the abyss of misery, according to the passion which he wishes to excite in his readers. In the modern novel, this hero or heroine is never placed on a throne or buried in a cottage; because to the monarch and the cottager no difficulties occur which can deeply interest the majority of readers. But amongst the virtuous part of the intermediate orders of society, that affection which we call *love* seldom fails, at some period of life, to take possession of the hearts of both sexes; and wherever it has place, it must be productive of happiness or of misery. In the proper management of this passion consists much of the difficulty of the novel writer. He must exhibit his hero as feeling all the pangs and pleasures of love, as sometimes animated with hope, and sometimes ready to sink into despair, but always exerting himself to obtain the gratification of his wishes. In doing this, care should be taken, either that he never transgress the laws of virtue, or that at least he never transgress them with impunity.

"It is justly considered," says the writer above quoted, "as the greatest excellency of art to imitate nature; but it is necessary to distinguish those parts of nature which are most proper for imitation: greater care is still required in representing life, which is so often discoloured by passion or deformed by wickedness. If the world be promiscuously described, I cannot perceive of what use it can be to read the account; or why it may not be as safe to turn the eye immediately upon mankind, as upon a mirror which shows all that presents itself without discrimination. It is therefore not a sufficient vindication of a character, that it is drawn as it appears; for many characters ought never to be drawn: nor of a narrative, that the train of events is agreeable to observation; for that observation which is called knowledge of the world will be found much more frequently to make men cunning than good. The purpose of these writings is surely not only to show mankind, but to provide that they may be seen hereafter with less hazard; to teach the means of avoiding the snares which are laid by treachery for innocence, without insuring any wish for that superiority with which the betrayer flatters his vanity; to give the power of counteracting fraud, without the temptation to practise it; to initiate youth, by mock encounters, in the art of necessary defence; and to increase prudence without impairing virtue.

"Many writers, for the sake of following nature, so mingle good and bad qualities in their principal personages, that they are both equally conspicuous; and as we accompany them through their adventures with delight, and are led by degrees to interest ourselves in their favour, we lose the abhorrence of their faults, because they do not hinder our pleasures, or perhaps regard them with some kindness for being united with so much merit. There have been men indeed splendidly wicked, whose endowments threw a brightness on their crimes, and whom scarce any villany made perfectly detestable, because they never could be wholly divested of their excellencies: but such have been in all ages the great corrupters of the world; and their resemblance ought no more to be preserved than the art of murdering without pain.

"In narratives, where historical veracity has no place, there should be exhibited the most perfect idea of virtue; of virtue not angelical, nor above probability (for what we cannot credit we shall never imitate), but the highest and purest that humanity can reach, which, exercised in such trials as the various revolutions of things shall bring upon it, may, by conquering some calamities and enduring others, teach us what we may hope, and what we can perform. Vice (for vice is necessary to be shown) should always disgust; nor should the graces of gaiety, or the dignity of courage, be so united with it as to reconcile it to the mind. Wherever it appears, it should raise hatred by the malignity of its practices, and contempt by the meanness of its stratagems; for while it is supported by either parts or spirit, it will seldom be heartily abhorred."

It is farther observed by Johnson, that the task of the novel writer "requires, together with that learning which is to be gained from books, that experience which can never be attained by solitary diligence, but must arise from general converse and accurate observation of the living world. Their performances have, as Horace expresses it, *plus oneris quantum variæ minus*, little indulgence, and therefore more difficulty. They are engaged in portraits of which every one knows the original, and can detect any deviation from exactness of resemblance. Other writings are safe, except from the malice of learning, but these are in danger from every common reader; as the slipper ill executed was censured by a shoemaker who happened to stop in his way at the Venus of Apelles.

"But the fear of not being approved as a just copier of human manners, is not the most important concern that an author of this class ought to have before him. Novels are written chiefly to the young, the ignorant, and the idle, to whom they serve as lectures of conduct and introduction into life. In every such work, it should therefore be carefully inculcated, that virtue is the highest proof of understanding, and the only solid basis of greatness; and that vice is the natural consequence of narrow thoughts; that it begins in mistake, and ends in ignominy; and since love must be introduced, it should be represented as leading to wretchedness whenever it is separated from duty or from prudence."

For some striking and profound observations on the effects of novel-reading, the reader is referred to what Mr Stewart has written upon that subject in his Elements of the Philosophy of the Mind. See the article ROMANCES.

NOVEL, in the civil law, a term applied to the constitutions of several emperors (*novellæ constitutiones*), more particularly those of Justinian. See CIVIL LAW.

NOVELTY, or NEWNESS. Of all the circumstances which raise emotions, not excepting beauty, nor even greatness, says Lord Kames, novelty has the most powerful influence. A new object produces instantaneously an emotion termed wonder, which totally occupies the mind, and for a time excludes all other objects. Conversation amongst the vulgar never is more interesting than when it turns upon strange objects and extraordinary events. Men tear themselves from their native country in search of things rare and new; and novelty converts into a pleasure the fatigues and even perils of travelling. To what cause shall we ascribe these singular appearances? To curiosity, undoubtedly; a principle implanted in human nature for a purpose extremely beneficial, that of acquiring knowledge; and the emotion of wonder raised by new and strange objects inflames our curiosity to know more of such objects. This emotion is different from admiration. Novelty, wherever found, whether in a quality or action, is the cause of wonder; admiration is directed to the person who performs any thing wonderful.

The pleasure of novelty is easily distinguishable from that of variety. To produce the latter, a plurality of objects is necessary; the former arises from a circumstance found in a single object. Again, where objects, whether co-existent or successive, are sufficiently diversified, the pleasure of variety is complete, though every single object of the train be familiar; but the pleasure of novelty, directly opposite to familiarity, requires no diversification.

However natural novelty may be, it is matter of experience, that those who relish it the most are careful to conceal its influence. Love of novelty, it is true, prevails in children, in idlers, and in men of shallow understanding; and yet, after all, why should one be ashamed of indulging a natural propensity? A distinction will afford a satisfactory answer. No man is ashamed of curiosity when it is indulged to acquire knowledge. But to prefer any thing merely because it is new, shows a mean taste, which one ought to be ashamed of. Vanity is commonly at the bottom, and leads those who are deficient in taste to prefer things odd, rare, or singular, in the hope of distinguishing themselves from others. In fact, this appetite reigns chiefly amongst persons of a mean taste, who are ignorant of refined and elegant pleasures.

Of this taste we have some memorable instances in men of the highest and the best education. Lucian tells a story of Ptolemy I. which is as disgraceful to him as it is honourable to his subjects. This prince had ransacked the world for two curiosities; one was a camel from Bactria, black all over, the other a man half black half white. These he presented to the people in a public theatre, thinking they would give them as much satisfaction as they did him; but the black monster, instead of delighting them, affrighted them; and the party-coloured man raised the contempt of some and the abhorrence of others. Ptolemy, finding the Egyptians preferred symmetry and beauty to the most astonishing productions of art or nature without them, wisely removed his two anomalous trifles out of sight; the neglected camel died in a little time, and the man he gave for a song to the musician Thespis.

NOVEMVIRI, nine magistrates of Athens, whose government lasted but for one year. The first of them was called *archon*, or prince; the second *basileus*, or king; the third *polemarchus*, or general of the army; the other six were called *thesmothetæ*, or lawgivers. They took an oath to observe the laws, and, in case of failure, obliged themselves to bestow upon the commonwealth a statue of gold as large as themselves. Those who discharged their office with honour were received into the number of the senators of Areopagus.

NOVI, a city of the duchy of Genoa, in Italy, now belonging to Sardinia. It is situated on the great road to Piedmont, has a strong castle, several churches, and 5572 inhabitants, who prepare some of the best silk in the district, in which they have a brisk trade, as well as in colonial productions.

NOVICE, a person not yet skilled or experienced in an art or profession. In the ancient Roman militia, *novicii* or *novitii* were the young raw soldiers, distinguished by this appellation from the veterans. In the ancient orders of knighthood, there were novices or clerks in arms, who went through a kind of apprenticeship ere they were admitted knights.

NOVICE is more particularly used in monasteries for a religious person still in his or her year of probation, and who has not made the vows. In some convents the sub-prior has the direction of the novices. In nunneries the novices wear a white veil, the rest a black one.

NOVICIATE, a year of probation appointed for the trial of religious, whether or not they have a vocation, and the necessary qualities for living up to the rule, the observance of which they are to bind themselves to by vow. The noviciate lasts a year at least, in some houses more. It is esteemed the bed of civil death to a novice, who expires to the world by profession.

NOVOGOROD. See NOWOGOROD.

NOWADAH, a town of Hindustan, in the province of Bahar, fifty-four miles south-south-east from Patna. Near it there is a pass through the mountains. Long. 85. 40. E. Lat. 24. 54. N.

NOWAGUR, a town of Hindustan, in the province of Gundwana, situated on the north-west bank of the Mahanuddy River. It belongs to the Nagpore Mahrattas, and is thirty miles south-south-east from Ruttunpoor. Long. 82. 55. E. Lat. 21. 55. N.

NOWED, in *Heraldry*, signifies knotted, from the Latin *nodatus*; being applied to the tails of such creatures as are very long, and sometimes represented in coat-armour as tied up in a knot.

NOWOGOROD, a province of Great Russia, which takes its name from the city which is now its capital, but was formerly that of the whole of Russia. The governments of Olonez, Pskow, Twer, and a part of that of St Petersburg, were included in it, till the recent divisions of the empire were established. It now extends between 57. 18. and 61. 8. north latitude, and between 20. 4. and 29. 41. east longitude, over 56,616 square miles. It contains ten cities, and 7932 villages, which are formed into 690 parishes, having each a church. The inhabitants are 964,500, and almost exclusively adhere to the Greek worship. The face of the country is level, though it includes the Waldai Hills; but none of these is more than 300 feet above the level of the sea. The soil in the northern part is marshy, and chiefly covered with moss; but in the south there is some dry and good land, the cultivation of which rewards the labourer, and the province produces more corn, chiefly rye, than it consumes. It also yields flax, hemp, and much wood. The climate is severe, being nearly similar to that

Nowogorod || Nuayhas.

of St Petersburg. The fisheries on the rivers and lakes yield much subsistence. There is but little commerce, and none but domestic manufactures.

NOWOGOROD, a city of Russia, the capital of a province, and of one of the thirteen circles of the same name into which that province is divided. It is situated in latitude 58. 32. 31. north, and longitude 31. 14. 16. east. It is the seat of the military government of Twer, as well as of both the military and civil governments of the province in which it stands. The site is on the banks of the Wolchow, where the water of the Ilmen is received into that stream, forming a river of more than a mile in breadth. The antiquities of the city are more striking than its beauties. The cathedral, with its brazen gates, is an object of curiosity for its venerable age, as is the tomb of St John of Nowogorod, a saint to whose shrine numerous pilgrims resort. It contains fifty-eight stone and four wooden churches, three monasteries, and 1550 houses, with 10,100 inhabitants. Though ill built, and with irregular narrow streets, it has an imposing appearance at a little distance, from the numerous spires and cupolas which are displayed. The chief occupations of the people are making sail-cloth and tanning leather.

NOWOGOROD SEWERSK, a circle of the Russian province Tschernigow, extending in north latitude from 51. 51. to 52. 24. and in east longitude from 31. 51. to 34. 19. The capital is a city of the same name, situated on the river Desna, 751 miles from St Petersburg. It is surrounded with walls, and has a castle, but neither in a good state of repair. It contains 1600 ill-built houses, with 8300 inhabitants, who carry on no manufactures, and subsist by trading in the productions of the surrounding soil. Long. 32. 48. E. Lat. 52. 50. N.

NOWOSILL, a circle of the Russian province of Tula, extending from north latitude 52. 53. to 53. 36. and from east longitude 37. 10. to 37. 25. and containing 94,600 inhabitants. The capital is a town of the same name, situated on the river Narutsha, 736 miles from St Petersburg, and containing 200 houses, with 1560 inhabitants. Long. 36. 55. E. Lat. 52. 55. N.

NOWPOORAH, a town of Hindustan, in the Mahratta territories of the province of Khandesh, forty-six miles east from Surat. Long. 73. 45. E. Lat. 21. 6. N.

NOX, in fabulous history, one of the most ancient deities amongst the heathens. She was daughter of Chaos, and from her union with her brother Erebus she gave birth to the Day and the Light. She was also the mother of the Parcæ, Hesperides, Dreams; of Discord, Death, Momus, Fraud, &c. Nox is called by some of the poets the mother of all things, of gods as well as of men; she was worshipped with great solemnity by the ancients, and had a famous statue in the temple of Diana at Ephesus. It was usual to offer her a black sheep, as she was the mother of the Furies; and a cock was also presented to her, as that bird proclaims the approach of day during the darkness of the night. She is represented as mounted on a chariot, and covered with a veil bespangled with stars. The constellations generally went before her as her constant messengers. Sometimes she is seen holding under her arms two children, one of which is black, representing Death, and the other white, representing Sleep. Some of the moderns have described her as a woman veiled in mourning, crowned with poppies, and carried upon a chariot drawn by owls and bats.

NUAYHAS, or AGUE TREE, a name given by the Indians to a sort of bamboo cane, the leaves of which falling into the water, are said to impregnate it with such virtue that the bathing in it afterwards cures the ague. To dissolve coagulated blood, they use also a decoction of the leaves, giving it internally, and at the same time rubbing with it the bruised part externally. It is said that this plant bears its flowers only once in its life; that it lives sixty years before the flowers make their appearance; and that, when they begin to show themselves, it withers away in about a month afterwards, that is, as soon as it has ripened the seed. There appears to be something of fiction in the account given of this tree in the *Hortus Malabaricus;* but it seems certain, that the length of the stalk, or trunk, must be very great. In the gallery of Leyden there is preserved a cane of nuayhas twenty-eight feet long; and another not much shorter, and more than eight inches in diameter, may be seen in the Ashmolean Museum at Oxford.

NUBA, a race of black Pagans, in the neighbourhood of Sennaar, of whom we know nothing, except what has been stated by Bruce. That traveller passed a day or two amongst them in his way from Abyssinia; and he tells us that they are all soldiers of the *melek* or king of Sennaar, cantoned in villages, which surround the capital to the distance of four or five miles. They are not the aborigines of that part of Africa; but are either purchased or taken by force from Fazuclo, and the provinces to the south upon the mountains Dyre and Tegla.

The idolatry of the Nuba is described as a mixture of Tsabaism and statue worship; but what is very uncommon, their worship is chiefly addressed to the moon, whilst they pay no attention to the sun either rising or setting, advancing to the meridian or receding from it. It is an old observation, that the worship of every people is tinctured by their natural dispositions; and this is verified in the case of the Nuba. "That their worship is performed with pleasure and satisfaction, is obvious," says Bruce, "every night that the moon shines. Coming out from the darkness of their huts, they say a few words upon seeing her brightness, and testify great joy, by motions of their feet and hands, at the first appearance of the new moon." This is just what we should have expected from their gentleness and hospitality. They likewise worship a tree and a stone, but our author could never discover what tree or what stone; he only learned that neither of them exists in Sennaar, but in the country where the Nuba are born. Such of them as are natives of the villages where he saw them, become, like their masters, nominal Mahommedans.

Boundaries and extent.

NUBIA, an extensive country of Africa, bounded on the north by Egypt, on the south by Abyssinia, on the east by the Red Sea, and on the west by the great Libyan desert. It is difficult to fix the precise limits and extent of this vast region, which will be variously estimated, according as we confine Nubia to the mere valley of the Nile between the first cataract and Meroë, or take into the account, as ought certainly to be done, the adjacent desert. There is, in fact, no principle of unity according to which it can be described as a whole; but, looking rather to the country itself than to any arbitrary definition or limitation, it may be considered as included between the thirteenth and twenty-fourth degrees of north latitude, and the thirty-third and thirty-sixth degrees of east longitude, and consequently as having a superficial area of not less than 360,000 square miles.

General character of the country.

With the exception of the immediate banks of the Nile, which are rendered partially productive by laborious irrigation, Nubia consists almost entirely of rocky and sandy deserts. From the southern boundary of Egypt to Derr, the capital of Lower Nubia, the mountains press so closely upon the river, that there is but little ground upon either side for the purposes of agriculture; and the small portion which is capable of being cultivated appears to be diminishing, from the gradual encroachment of the sands, which the winds of the desert carry towards the stream. The peculiar structure of the valley through which the Nile here forces a passage, renders it obvious that there could not at any period have been a very dense population in this part of Nubia. But farther up the river, beyond the parallel of Wady Halfa, there is ample space for the powerful nations which are said to have flourished here in ancient times. At the second cataract immense plains stretch out from either margin of the stream, exhibiting, it is said, even in their present neglected condition, unequivocal indications of fertility; and as there seems to be little doubt that, in former ages, the annual inundation extended considerably beyond the limits of modern cultivation, so it may reasonably be presumed that, anciently, the country was much more productive and populous than in modern times, when the decrease of the inundation, and the continual encroachment of the moving sands on the side both of the Nubian and the Libyan deserts, have combined to produce the desolation which now prevails. At present the Nile seldom or never overflows its banks in this part of Nubia; and the portion of the soil cultivated is irrigated by means of *sakkeas* or Persian wheels, constructed for raising the water of the river to the level of the adjacent ground. The eastern bank of the Nile is much better adapted for cultivation than the western, being more easily irrigated by artificial means. But it is not a little remarkable, that all the splendid ruins for which this region is distinguished, and which exhibit so great labour, ingenuity, and skill, are found upon the opposite bank; a circumstance which seems to strengthen the presumption that Nubia was formerly much more fertile and populous than in the present day.

The country on the banks of the Nile is divided into a number of little independent principalities, each governed by its own *melek* or chief. But, taken as a whole, it is composed of two parts; Wady Kenous, and Wady Nouba. The former extends from the confines of Egypt on the south to Wady Seboua; and the latter, from which the general name of the country appears to have been derived, stretches as far as the frontier of Dongola. The chief distinction between these two parts consists in the circumstance, that the languages spoken in each are entirely different. The governors of the various districts are described as ferocious and arbitrary in their proceedings; rude in their treatment of strangers, whom they regard with suspicion; and addicted to most of the vices which are common amongst barbarians. They acknowledge a nominal subjection to the viceroy of Egypt, but seldom neglect any opportunity that offers of setting his authority at nought. Still, under the safeguard of his firman, Europeans may travel as far as Ibrim (the ancient *Primmis*) in perfect safety; but, beyond that point, they must lay their account with being exposed to the vexations and dangers usually incurred in visiting barbarous countries, especially in Africa. In the marauding, slave-hunting expedition of Ismael Pasha in 1821, the treatment which the natives everywhere experienced has had the effect of exasperating and confirming the hostility of all the tribes who inhabit the upper parts of Nubia; nor is it likely that the remembrance of the wanton aggression which was then made upon them will soon be effaced from their memories. Each of the Nubian sheicks pays an annual tribute to the viceroy of Egypt; or rather a certain sum is extorted as an acknowledgment of subjection, and the price of an immunity from a visit by the viceroy's troops.

The grain which forms the principal object of Nubian cultivation is dhourra, the *holcus arundinaceus* of the botanists. It is raised upon the patches of soil irrigated by means of the sakkeas or Persian wheels, of which there are from six to seven hundred between the first and second cataracts; and, when ground, it is formed into a cake somewhat resembling the Abyssinian *teff*. But as the people have no mills of any kind wherewith to grind it, this is usually effected by placing the grain in small quantities upon a large stone, and rubbing a smaller one over it until it is reduced to a sort of flour. If it be intended to produce bread of a superior quality, the dhourra is well washed, and then dried in the sun. But in general the people do not take this trouble; and the meal produced by their rude mode of grinding resembles a paste of the coarsest kind, mixed with chaff, sand, and dirt. It is usually placed in an earthen jar, and there left to ferment during twenty-four or thirty hours, after which time it acquires a subacid taste. No leaven is formed. A portion of the fermented pulp is merely poured upon an iron plate or stone placed over a fire, and in a few minutes it is baked into a cake; and this is repeated till the whole be baked. Cakes are usually brought hot to table, in a wooden bowl, with onion sauce, broth, milk, or butter poured on them; but some of a thinner kind, and well toasted, are prepared for the use of the caravans, and may be kept without being spoiled for several months. After the dhourra, the Nubians raise a crop of barley, French beans, lentils, and sometimes also of water-melons. Tobacco is everywhere cultivated, and constitutes the principal luxury of all classes, being either smoked, or sucked in a peculiar manner between the gums and the lip. Animal food is scarce, and seldom eaten, even by the chiefs or sheicks. The liquors used are palm wine, a spirit distilled from dates, and a sort of beer called *bouza*, which is made from dhourra. Excessive indulgence in these liquors is general throughout the whole country. The only fruit trees cultivated in Nubia are palms, but the soil is adapted for several others. Great sameness prevails in the vegetation of the desert, the trees being mostly acacias, tamarix, date, and domm palms.

Climate.

The climate of Nubia, though intensely hot in summer, is nevertheless remarkably healthy. This is no doubt a consequence of the extreme dryness of the atmosphere, occasioned by the absence of rain, and the absorbent qualities of the soil. The plague has seldom or never reached Wady Halfa, and beyond the second cataract it is entirely unknown. The small-pox, however, is a fearful scourge, and, owing to the ignorance and filthiness of the people, occasionally commits dreadful ravages. The houses of the Nubians are constructed of mud or of loose stones. The mud huts are roofed with dhourra stems or palm leaves, which in this climate are found to be a sufficient covering. The houses which are built of stones, being for the accommodation of the better class of inhabitants, commonly consist of two compartments, one for the male and the other for the female members of the family. The utensils of a Nubian household are few and wretched; half a dozen coarse earthen jars, some earthen plates, two stones for grinding dhourra, and a few round sticks, usually constituting their whole stock. From this an idea may be formed of the miserable condition of the inhabitants, as compared with those of any other country, Egypt only excepted.

Population.

Still the Nubians are generally well made, strong, and muscular, and have tolerably good features. The women are not handsome, but perfectly well formed, and in general remarkable for agreeable countenances and pleasing manners. They are also modest and reserved, and strictly observant of their conjugal duties. The domestic employments of the women consist chiefly in weaving coarse woollen mantles, cotton cloth for shirts, and mats of the date leaves; they also make drinking-bowls, and plates for containing the dhourra bread. A linen cap and a woollen cloth or mantle constitute the dress of the rich. The women usually wrap themselves in black woollen gowns; but children of both sexes run about quite naked. In ascending the Nile to Sukkat and Mahas, the dress becomes more and more scanty, and at length almost entirely disappears. The Nubians are seldom seen unarmed; indeed the first purchase made by a boy is that of a short crooked knife, which being fastened at the left elbow, is ready to be drawn on the slightest quarrel. Fire-arms are not common, and ammunition is very scarce. The inhabitants of the two divisions of Nubia, Wady Kenous and Wady Nouba, are almost constantly engaged in sanguinary quarrels; and when

Nubia.

death ensues, as is not unfrequently the case, the family of the deceased may either demand the price of blood, or retain the right of retaliation, which may be enforced against the brother, son, or first cousin of the murderer, at the option of the avenger. The consequence of this is, that when a death has occurred in any of these quarrels, a whole family is often obliged to leave the country. Great numbers of the Nubians repair to Cairo, where they usually act as porters, and are esteemed for their honesty; but they always return to their native villages with the little property which they have saved in plying their humble vocation. The inhabitants of Derr-el-Mahas and the more southerly districts differ considerably from the other Nubian tribes. Their houses are constructed only of palm leaves, fastened to high poles, the extremities of which rise considerably above the roofs. The countenances of the people are much less expressive of good nature than in the lower parts of the country, and their character corresponds with this difference of expression. In colour they are perfectly black, and their lips are thick like those of the negro, but they have not the same flat nose and high cheek-bones. A number of the men, and even girls who have attained womanhood, go about quite naked. Burckhardt has described the king of the Mahas as a mean vulgar-looking black, attended by some half dozen naked slaves, armed with shields and lances. Mahas is the nearest place in the country of the blacks, from which slave traders proceed to Cairo, a distance of about a thousand miles.

Tract between the Nile and the Red Sea.

There is another part of Nubia which is well deserving of particular notice; we mean the vast tract of country extending from the Nile to the Red Sea, between the parallels of 23° and 15° of north latitude. Modern travellers have penetrated this extensive region only by one line, namely, that which is followed by the Nubian caravans proceeding from Egypt to Sennaar. It is described as throughout a complete desert, without even a single fixed habitation, but interspersed with *wadys* or valleys, producing some trees, shrubs, or grass, and usually containing a few wells or rills, which are resorted to by the wandering Arabs, and also by the caravans, for a supply of water. The want of this important article forms the chief danger attending the journey; but if due precautions be taken, and the water-bags be properly filled at the wells, travellers can never be reduced to a state of great suffering, as many days seldom elapse without the means of obtaining a supply. Burckhardt, after having passed through the deserts of Suez and Sinai, did not consider this tract as quite so dreary, although its aspect is much more rugged, being in general hilly. At the southern extremity of this desert, through which roam the Bishareen tribes, is the district of Berber, consisting of four large villages, the inhabitants of which are chiefly employed in carrying on the trade of Egypt and Arabia with the interior of Africa. The people are a very handsome race, of a reddish-brown colour; which, if the mother be a slave from Abyssinia, becomes a light brown, but if from the negro countries, extremely dark, indeed almost black. The men are somewhat taller than the Egyptians, and also better limbed, and more muscular. Their features bear no resemblance to those of the negro; the face being oval, the nose often perfectly Grecian, and the cheek-bones by no means prominent. They consider themselves as Arabs, not negroes, and are very careful in maintaining the purity of their race. A free-born Meyrefab never marries a slave, whether Abyssinian or negro, but always an Arab girl belonging to his own or to some neighbouring tribe. Few men have more than one wife; but every one who can afford it keeps a female slave or mistress, either in his own or in a separate house; and traders passing through Berber usually take a mistress during the period of their stay in the district. Drunkenness is the constant companion of this debauchery; and these dissolute habits produce the most pernicious effects on the morals and conduct of the people. Their character indeed is deformed by every degrading and debasing vice; they are noted for treachery and dishonesty; in the pursuit of gain they are restrained by no principle, breaking without scruple the most solemn engagements; and in transactions amongst themselves they commonly terminate every dispute by the law of the strongest. Quarrels are frequent and violent at drinking parties, and mostly end in bloodshed either with the knife or the sword. The principal scenes of these disorders are the *bouza* huts, which are kept by women of infamous character, by whom the liquor is also manufactured. Indeed no one ventures to enter one of these without his sword, and several persons of distinction have been killed in them. In a word, it is marvellous that a people so completely abandoned to the dominion of the most brutal passions have not long since been consumed by their own vices. Another part of this territory is the district of Taka, inhabited by the Bishareen Arabs. It is comparatively populous and fertile, differing in many respects from the other parts of Nubia; and through it passes the road to Souakin, followed by Burckhardt, the first who made us acquainted with Taka.

Government.

The government of Nubia, like that of Egypt, is essentially military. The officers, all of whom are Turks, decide every question connected with the revenues, and frequently interfere, in other affairs, with the decisions of the cadis or civil judges. The system of the government is to extort from the peasant the utmost possible amount in the shape of taxes, leaving him only what is considered a sufficient subsistence, which, as might be expected, is usually a most miserable one. In some places, indeed, if the peasants did not actually steal from their own fields, they could not exist; and although they bury their grain under ground, and by various other methods deceive their oppressors, yet numbers perish from the want of sufficient sustenance and clothing. A vast proportion of the peasants subsist on food which is more calculated for cattle than human beings; and even of this, bad as it is, they have rarely enough. The pasha has power enough to keep them in subjection, and by his extortions fills his coffers. He not only imposes enormous taxes on every article of produce, but obliges the people to cultivate whatever he chooses, and to take the price which he offers for the produce. He is the only purchaser of the grain, cotton, and indigo, the gum of Kordofan, ostrich feathers, and other articles. Slaves are almost the only commodity which the merchants are allowed to take in exchange for the manufactures which they carry to Kordofan and Sennaar; and even the wild animals of the desert, as the giraffe, form a government monopoly. The pasha is also the landlord or proprietor of this immense region; and the people are his slaves. His revenues are derived not only from the regular taxes, but likewise from his profits as a merchant, which are enormous, owing to the low rate at which he pays the peasants for their produce, compared with the high price at which he afterwards sells it to Europeans. This source of gain, however, is greatly diminished by the roguery of the different officers through whose hands the various commodities pass. From the highest to the lowest there is no exception in this respect; mahmours, nayrs, kiachefs, caimacans, and mallums or Coptic accountants, all concur in diminishing the amount, and sharing the plunder of the unhappy peasantry. The Copts employed in this department not only cheat the ignorant Turks, who generally cannot read their accounts, but often trade with the money of the treasury, and sometimes incur losses they are unable to make good; on which account numbers of them are always immured in the prisons of the viceroy.

Condition of the people in Upper Nubia.

But the peasants in Upper Nubia are free from these exactions, and therefore comparatively happy. It is no doubt true, that, instead of one dollar in money, two pieces of linen cloth, and a sheep, which was all they paid their ancient meleks, they are now obliged to pay fifteen dollars in cash and five in grain, being in all three hundred piastres, or ten times the amount of their former contributions; and they are likewise obliged to work instead of sleeping during the greater part of the day, as was formerly their custom when under their own chiefs. But the man who is at all industrious may nevertheless earn what is amply sufficient to afford him food, and such dress as he has been accustomed to. Each sakkea or Persian wheel is sufficient to water three quarters of a feddan of land, planted with indigo; and each feddan, when carefully irrigated, produces a hundred cantars of the herb, and sometimes more, being about seventy-five cantars for the extent of land which one wheel will water. The government pay the peasant 12½ Egyptian piastres for each quintal, or 937 piastres for the whole; which, at the current rate of the dollar in this country (fifteen piastres), is equal to 62½ dollars. If from this we deduct twenty dollars for the duty, there remains for the persons to whom the wheel belongs 42½ dollars, or 637 piastres; but as the calculation here made is at the lowest rate, two piastres a day may fairly be estimated as the clear gain of the peasantry by each water-wheel. This sum, small as it may appear, is sufficient for the support of one family, provided it contain five persons capable of putting their shoulders to the wheel; if it do not, however, two families must unite to make up this number. The immense expense of the water-wheel forms a great deduction from the gain of the peasant in Egypt; but in Nubia they are so much more simple that they cost only a trifling sum, as oxen may be obtained for thirty piastres each, whilst their "keep" is next to nothing. Two piastres, or sevenpence sterling, may appear a very small sum to a European; but in this country, where every necessary is so cheap, it is amply sufficient for the support of a family. In both divisions of Egypt, where bread is much dearer, and meat and milk are double the price, the fixed remuneration of a labourer amounts to only half a piastre per day, with which he has to sustain himself and perhaps a family. But in Nubia most of the peasants have slips of land watered by the partial inundation of the river, and gain considerably by their date trees, although they pay a tax of a piastre for each. They also rear flocks; cultivate vegetables, particularly bamia and malakhia; and make linen, spirit, bouza, and other articles. The condition of the peasants of Upper Nubia is therefore happy, compared with that of the Fellaheen of Egypt, the most oppressed and degraded population in the world.

The Arabs of the desert have still more reason to be satisfied with the government. They pay tribute only for the land they cultivate, which is in general very little, and in many cases none at all; and otherwise they gain a sufficient livelihood by transporting to Egypt on their camels the grain collected as revenue, or purchased by the government, and by aiding the passage of troops and merchants, which is now unintermitted. As far as regards taxes, and the means of subsistence, therefore, the Arabs of the desert in Upper Nubia, as well as the peasants on the Nile, are in a much better condition than the Fellaheen of Egypt. But in all other respects they are equally galled and insulted by their Turkish rulers. In Egypt, the officers only are oppressive, and the soldiers, who mostly belong to the class of Fellaheen, are not insolent. In Nubia, however, it is far otherwise. The comparatively white complexion of the troops, their character as conquerors, and their pride as *askaria* (soldiers), induce them to despise the natives, and exercise oppressions which the government by no means authorizes. When the chief governor of a province is a man possessed of talent, energy, and firmness of character, the officers and soldiers are prevented from committing many excesses. But when the country has the misfortune to be governed by an individual destitute of the qualities we have mentioned, and too timid to redress the grievances occasioned by the disorderly conduct of the troops, its state may easily be imagined. Every evil is then aggravated by impunity. Men whose ancestors have been meleks or chiefs in the country for ages, are obliged to submit to the insolence and tyranny of a lawless soldiery. Taxes oppressive in themselves are rendered tenfold more so by the mode in which they are levied. Every collection is a species of military execution. No proper notice is almost ever given. "Pay to-morrow, or the bastinado," is the usual intimation conveyed to the peasant, who, not being allowed sufficient time to raise the money, is subjected to this cruel and degrading punishment, and sometimes nailed by the ear to a board. The revolt of the Mahas, described by Mr Hoskins, was occasioned by this summary mode of collecting some arrears of taxes.

General remarks.

Nubia, under proper management, might become a far greater source of wealth to the ruler of Egypt than it now is, or seems likely to be, under his sway. His system is one which is not only calculated to defeat its own objects in a fiscal point of view, but to exasperate the natives, whom good policy would try to conciliate, and also to sow the seeds of future anarchy and convulsion. At the same time, notwithstanding the galling conduct of the Egyptian authorities, the natives are sensible of the advantage of a firm and settled government; and the peasants of the Nile, in particular, are glad to be released from the tyranny and spoliation which accompanied the feuds and petty wars by which the country was formerly distracted. "Did the Turks," says Mr Hoskins, "but treat them as men, and not disgust them by their insulting manners, and by inflicting on them such degrading and infamous punishments; had their rulers but a few ideas of common policy and legislation; the resources [of the country] might be greatly augmented, the revenue increased, and the people the most happy and contented under the sun. The superiority which fire-arms afforded to their haughty conquerors taught them to despise the strength of the Arabs; and, with that insolence which is ever united with ignorance, they do not, in the slightest degree, endeavour to attach them to the government, or, in fact, condescend to treat, otherwise than as a vastly inferior race, the people whom it cost them so much, with all their advantages, to conquer."[1]

Trade.

The chief trade of Nubia, as already mentioned, consists in slaves imported from the interior of Africa, and either conveyed northwards to Egypt, or sent across the Red Sea from Souakin to Jidda. The annual import is estimated at about 5000, of whom 2500 are for Arabia, 1500 for Egypt, and 1000 for Dongola and the Bedouins of the mountains. Few of the slaves are above the age of fifteen; but the most valued are those between eleven and fifteen, who, if males, sell for fifteen or sixteen dollars, and if females, for twenty-five or twenty-six. In the East, slaves are chiefly employed as domestics, and people are seldom fond of any who have not been in the family from an early age. These children, as long as they remain within the negro territories, are treated with great indulgence; but when they once enter the desert, and have no longer any chance of escape, this treatment is entirely changed, and the lash unsparingly applied. The health of the slave, however, is always attended to; he is regularly fed, and receives a share of water with his master. Dates, gums, and ostrich feathers are also exported; as are senna leaves, ebony, sandal-wood,

[1] Hoskins, Travels in Ethiopia, pp. 230, 236.

Nubia.

and some other articles, though in small quantities. Gold is found in mines, and amongst the river sands, but not in such abundance as to form any considerable article of exchange.

Monumental remains of Nubia.

One of the most remarkable features of this region consists in the magnificent monumental remains with which it is covered along the line of the stream, and which continue to perpetuate the genius and power of the ancient population of the country situated on the Upper Nile. That Egypt was indebted to Ethiopia (which included Nubia) for the rudiments, and perhaps even for the finished patterns, of architectural skill, is no longer questioned by any writer whose pursuits have qualified him to form a judgment of the subject. Gau, in his splendid work on Nubia, maintains it as a first principle, that this country was the cradle of Egyptian architecture; and its monuments embrace the whole period during which the art flourished in the valley of the Lower Nile. He conceives that all the architecture of Egypt, from the first rude effort to cut a temple in the rock, to the construction of those detached edifices which were afterwards erected in the times of the Greeks and Romans, has its types in the structures of Nubia. Hence, in the architectural history of that country, he distinguishes three great epochs; the first comprehending the temples cut in the sides of the hills or rocks, which are evidently the most ancient; the second, those which are detached from the chambers cut in the rock, but still retain the colossal masses of the primitive type; and the third, the small edifices of Maharraga, Gartaas, and Dondour, with several analogous structures in Egypt. This classification appears to be perfectly natural and well founded, inasmuch as the only test of the relative antiquity of such monuments is a reference to the comparative simplicity of their structure or formation. It is upon this principle, therefore, that we shall now proceed to describe very shortly, some of the principal temples and other edifices in Nubia.

Temples of Gibel-el-Birkel, &c.

At Gibel-el-Birkel, Waddington discovered two temples excavated in the solid rock, and having only their exterior chambers formed of masonry; circumstances in which they resemble those of Girshé, Seboua, and Derr. The smaller of the two has six halls or apartments, five of which are cut in the body of the mountain; the larger, constituting the entrance, stands on an artificial foundation of stone, by means of which it is raised as high as the rock in which the other is excavated. Near the adytum there are figures of Ammon and of Horus; and vestiges of hieroglyphics may be discerned in all the chambers. From the plainness of the masonry, the rudeness and decay of the sculptures, and the decomposition of the walls, it has been concluded that this is older than any of the temples of Egypt, or even of Nubia. The temple of Girshé also belongs to the more simple order of structures, and indicates a rude state of the arts connected with architecture. The portico consists of five square columns on each side, cut out of the rock, with a row of circular pillars in front, constructed of several blocks, and originally surmounted with an entablature, though only two of them now remain. Before every one of the square columns stands a colossal statue of sandstone, eighteen feet in height, holding a lash or flail in one hand, and the other hanging down; the figure of each is that of a male, with the pointed beard under the chin, the high sphinx-cap on the head, and the shoulders covered with hieroglyphical inscriptions. On both sides of the portico there is an open alley, which is hewn in the rock. The pronaos, eighteen yards square, is entered from the portico, and contains two rows of immense columns without capitals, in front of each of which there is a colossal figure, more than twenty feet in height, with the hands crossed on the breast, and holding the flagellum in one, and the handled cross, or emblem of life, in the other. On the side walls are four recesses or niches, in each of which are three statues of the natural size, representing the different figures, male and female, which are observed upon the walls of the temples of Egypt. A door leads from the pronaos into the cella, in the middle of which there are two massive pillars, and, upon either side, a small apartment. Very little is now discernible of the sculpture and hieroglyphics with which the walls were covered; but enough remains to show that they were very rudely executed.[1] The ruined structure at Seboua has before it a propylon similar to that of Gourneh at Thebes. The pronaos on each of its longest sides has five columns without capitals, and in front of each is a colossal figure, sixteen feet in height, with the arms crossed on the breast, and the usual emblems in the hands. Before the entrance there lies on the ground a huge statue, the head and bust of which are buried in the sand; and in front of the propylon are two statues, ten feet in height, with their faces towards the river, and attached by the backs to stone pillars of equal elevation. An avenue of sphinxes leads from the bank of the Nile to the temple, but the greater part of them are now buried in the sand, four only remaining visible. The whole fabric appears to be of the remotest antiquity, and has been imitated by the more modern architects of Egypt.[2]

Temple of Ebsamboul.

But of all the rock temples of Nubia, that of Ebsamboul or Ipsamboul,[3] about a day and a half's journey below the second cataract, is incomparably the most remarkable. In the course of centuries the sand of the desert had so completely overwhelmed it, that nothing appeared to the eye of the traveller except the bust of one of the colossal figures which were placed at the front of the entrance. But the dimensions of this statue were so great as to excite the curiosity of all who examined it; and the countenance, when seen at a proper distance, appeared strikingly beautiful. Animated with a desire to explore the buried structure of which this statue formed an exterior ornament, a party, consisting of Mr Belzoni and Captains Irby and Mangles, with some attendants, undertook to remove the sand, so far at least as to ascertain whether there was a door-way, or any other access to the interior. At first they relied upon the assistance of the natives, who readily entered into terms with them; but the increasing fatigue, and an evident disinclination to the work, induced the Nubians to break their engagement, and the travellers had no resource but to complete the labour with their own hands. In the hot season of the year, and with a scanty supply of necessaries, they worked day by day in the sand, from sunrise till night; and at length, after more than three weeks of continued exertion, each performing the labour of about a dozen Nubians, a corner of the door-way became visible; and an entrance having been effected, the interior was explored, probably for the first time during a thousand years.

The first glance at the interior convinced Belzoni and his associates that it was evidently a very large structure; but their astonishment increased when they found it to be one of the most magnificent of temples, enriched with

---

1 This is the same place which by other travellers is called Guerfeh Hassan, or Gwersh Hassan, and is described with much minuteness in several of their works. (See Henniker, Notes, &c. p. 154.)

2 The propylon and pronaos are found, on a large scale, at Gourneh, near Thebes; the two statues in advance of the propylon are the miniatures of those in front of the Memnonium; and the sphinxes are seen are Karnak.

3 The name, as spelled by Belzoni, is *Ybsambul*, whilst others write it *Ebsamboul* and *Ibsamboul*. But all these forms are probably corruptions of *Abou-Sambul*, which appears to be the genuine name.

beautiful intaglios, paintings, and colossal figures. The pronaos, fifty-seven feet in length, and fifty in breadth, is supported by two rows of square pillars in a straight line from the front door to that of the sekos; and each pillar has attached to it a figure finely executed, and very little injured by time, the top of the head-dress reaching the ceiling, which is about thirty feet in height. Both the pillars and the walls are covered with representations of battles, storming of castles, triumphs, and sacrifices, in a style, if not superior to, at least bolder than, that of almost any in Egypt, both in regard to the design and the workmanship. The second hall, which is of less dimensions, contains four pillars about four feet square, and the walls are covered with hieroglyphics in tolerable preservation. Beyond this there is a chamber of the same width, but shorter, in which is the entrance to the sanctuary; and at each end is a door leading into smaller apartments in the same direction with the adytum. The sanctuary itself is twenty-three feet in length by twelve in breadth, and contains a pedestal in the centre, with four colossal figures in a sitting posture at the end, all in good order, and uninjured. On the right side of the great hall there are two doors at a short distance from each other, and which lead into two separate apartments of considerable dimensions, at the end of which are several unfinished hieroglyphics, sketched so as to give an idea of the manner of drawing. At the lateral corners of the entrance from the first into the second chamber are doors, each of which leads into a chamber twenty feet by ten; and these again open into other apartments, forty-three feet in length by eleven in breadth. The most remarkable subjects in this temple are a group of captive Ethiopians in the western corner; a hero killing a man with his spear, and another lying dead at his feet; and the storming of a castle, which forms part of the representation. The outside or external front of this temple is truly magnificent, being a hundred and seventeen feet in width, and eighty-six feet in height, whilst the space from the top of the cornice to that of the door is sixty-six feet and a half, and the height of the door itself twenty feet. There are four enormous sitting figures, the largest in Nubia, or even in Egypt, excepting only the great sphinx at the Pyramids, to which they approach in the proportion of nearly two thirds. On the top of the door is a statue of Osiris, twenty feet in height, with a colossal figure on each side looking towards it. The cornice of the temple is adorned with hieroglyphics, and under it are a torus and frize, the one six and the other four feet in breadth. Above the cornice is a row of squatted monkeys, twenty in number, and each eight feet and a half across the shoulders. This temple was nearly two thirds buried in the sand, of which thirty-one feet were removed before reaching the upper part of the door. It is excavated in the solid rock, which here rises about a hundred feet above the Nile, and, excepting one of the tombs at Biban-el-Molouk, is the largest of the kind either in Egypt or Nubia.[1]

At a subsequent period, Mr Bankes visited Ebsamboul, and succeeded in uncovering down to the feet one of the four colossal sitting figures, upon the limbs of which he discovered and copied an inscription in Greek relating to Psammeticus. He next cleared the head of the fourth colossal figure, which had not before emerged above the surface, so as to be able to make a drawing of the whole; and the approach being thus disencumbered, the interior of the temple was lighted up with wax candles fixed on upright poles, to enable Mr Bankes and his assistant draughtsmen to copy all the paintings in detail. It is much to be regretted that the labour in opening this temple has not been attended with any permanent effect; the winds of the desert and the natural lubricity of the sand having soon rendered the approach nearly as difficult as before. In about two years the door-way was again covered up, and by this time the interior must be quite as inaccessible as ever. All travellers agree in the accounts they give of Ebsamboul, which is described as the *ne plus ultra* of Egyptian labour. According to Sir Frederick Henniker, there is no temple at Denderah, Thebes, or Philae, that can be put in comparison with it; and the traveller just named rejoices in "having seen the noblest monument of antiquity that is to be found on the banks of the Nile." This is not the place to enter into details respecting the hieroglyphical emblems and inscriptions with which different parts of this wonderful structure are covered. The larger chamber is distinguished as the temple of Osiris, and the smaller as that of Isis, to whom it is dedicated. The former is represented in a sitting posture, attended by the hawk-headed deity; whilst the latter holds in her hand the lotus-headed sceptre, surrounded with numerous inscriptions and emblems. Much interesting sculpture is also lavished upon the second and third apartments; and in a niche at the upper end of the latter is a small statue of Nephthe, the wife of Typhon, seated. In several places of the square border which encircles the front of the temple, and also on the buttresses between the colossal figures, are a number of ovals or rings, containing the name and prænomen of Ramesses the Great, the same Pharaoh whom the Greeks indicate by the name of Sesostris or Sethosis. We may here add, that a striking resemblance has been observed between the rock temples of India, particularly that in the island of Elephanta, and those of Nubia, especially that of Ebsamboul; indeed the similarity is so great as to have suggested the notion of a common origin, as well in regard to the mythology as the architecture of both countries.[2]

Temples of Samneh, Dondour, &c.

The temple of Samneh, situated on the western bank of the river, between the twenty-first and twenty-second degree of north latitude, affords a specimen of a more perfect class of structures; intermediate, it would seem, between such excavations as that of Ebsamboul and the magnificent edifices of Karnak and Luxor. It is built of sandstone, and differs in shape from other edifices of a similar kind, though in its plan it somewhat resembles the small chapel at Elephantina in Egypt. The principal building is about thirty-six feet in length and nine in breadth. On either hand there stood originally four small pillars, of which two remain on the one side, and three on the other, all covered with sculptures. The inner walls are adorned with hieroglyphics and mystic representations, amongst which may be mentioned the ship of Osiris; and upon the outer wall Burckhardt's distinguished figures of Mendes. The sculptures are rather coarsely executed, and the lines dividing the columns of hieroglyphics, some of which have been left unfinished, are not straight. The temple of Dondour or Tangour is likewise deserving of attention, from the peculiarities of its style, having been classed by Gau amongst those structures which belong to the last of the epochs of Nubian art already mentioned. It is in form a parallelogram, having the proportions observed in some Grecian structures; and in the pillars may be recognised the mixed Greek and Egyptian style. Between the second and third cataract, in latitude twenty-one degrees north, is the temple of Soleb or Solib. An elevated stone foundation extends in front of the temple, and the remains of two sphinxes are seen at either side of the approach. The first

[1] "The heat was so great in the interior of the temple," says Belzoni, "that it scarcely permitted us to take any drawings, as the perspiration from our hands soon rendered the paper quite wet. Accordingly, we left this operation to succeeding travellers, who may set about it with more convenience than we could, as the place will become cooler." (Narrative, p. 214.)

[2] See Erskine's Account of the Cave-Temple of Elephanta, in the Transactions of the Literary Society of Bombay, vol. i. pp. 210, 249.

Nubia.

chamber is more than a hundred feet in breadth, and about ninety feet in depth, having round three of its sides a single row of pillars, and on the fourth indications of a double row. They have all been executed from the same model, and are inscribed with hieroglyphics. In the second chamber may be traced a row of pillars, resembling those of the first; but they are all broken, and the fragments scattered about in every direction. The dimensions of the adytum cannot now be ascertained, the side walls having been completely destroyed. The temple of Soleb affords the lightest specimen anywhere to be seen of Ethiopian architecture, and, for elegance of proportion, has been compared to that of Minerva Sunias at Cape Colonna. At Gibel-el-Birkel there are the remains of two temples, partly excavated in the rock, and partly constructed, like those of Girshé and Seboua. The principal temple is of vast dimensions, and contains no less than six chambers. It is supposed to have been the work of different and distant periods; and, even in the construction of those parts which belonged to the original building, many stones were employed which had formed parts of some more ancient edifice. The vicinity of Gibel-el-Birkel is remarkable for pyramids, which, though much inferior to those of Egypt, probably originated in the same views of vanity or superstition, not to say tyranny. For further information on the subject of Nubian rock excavations and architecture, the reader is referred to the works of Burckhardt, Light, Legh, Richardson, Henniker, Caillaud, Waddington, and Hoskins, in which will be found ample descriptions of the remains on either side of the Nile, from Assouan to Meroë, accompanied occasionally with drawings and plans. The reader is also referred to the articles Ethiopia, Ethiopian Nations, and Meroe.

General deductions.

On the whole, it appears that, by a more accurate classification of the monuments, and the aid of inscriptions, which to former travellers were altogether unintelligible, we are now enabled to rectify misconceptions, correct mistakes, discard mere conjectures, and, in fact, make a real and valuable addition to the history of civilized Egypt. Between the temples excavated in the rock, such as those of Derr and Ebsamboul, and the buildings of a later date, there was an intermediate stage in the art, which it is important to distinguish. The first architectural attempt in Nubia probably consisted in the improvement of some hole or cave in the rock; or, even if the country possessed no natural caves for imitation by a people possessing the troglodyte habits natural to the inhabitants of a burning climate, the mountains themselves would afford facilities for constructing durable habitations. After having got possession of a hole or cave, the next step of these primitive architects would probably be to extend the excavation, to form several chambers separated by the native rock, and when a compartment of larger dimensions was designed, to have square pillars for the support of the roof. In the course of time the outer front, with the inner walls and pillars, would receive decorations derived from imitations of the natural forms of the country, and subjects connected with the historical remembrances or religious creed of the nation. We see abundant evidence in the rock temples of Nubia to convince us, that the order of progression and improvement here indicated was that actually followed in their gradual enlargement and decoration; yet a prodigious period must have elapsed between the rudest excavation in the rock, such as Derr appears to have been in its primitive state, and the highly-finished sculptures of the great temple of Ebsamboul. In fact, "antiquity appears to have begun" long after these primeval architects had commenced their troglodyte labours. But, in surveying the wonders which crowd the banks of the Nile from Meroë to Memphis, our minds become insensibly impressed with the reflection, that the wealth, power, and genius which produced them have entirely passed away; that, if the new worlds have risen, and new races been discovered, "we have lost old nations;" and that, in the lapse of ages, empires themselves vanish, like the baseless fabric of a vision, leaving scarcely a wreck or trace behind them. Throughout many parts of this extensive tract, a race little superior to savages pass a rude and precarious life, ignorant of the arts which once flourished in their country, and insensible to the beauty and magnificence of the ruins which they desecrate. They have long ceased to claim any connection with the people who constructed the monuments of Ebsamboul, Karnak, Luxor, and Gourneh; and having relapsed into that low condition where curiosity becomes dormant or extinct, they are only moved with wonder when they observe the natives of civilized regions exploring their temples, or taking the dimensions of their obelisks and pyramids. The contrast between what now is, and what once must have been in Ethiopia and in Egypt, is indeed most striking; nor is it easy to pass, even in thought, through the various scenes of conquest and desolation which must have conspired to produce the effects we contemplate. History sheds no light on events and characters which the lapse of three thousand years has covered with impenetrable obscurity; and whilst groping our way amidst temples dedicated to gods, and structures raised in honour of heroes, whose very names sound like voices from the dead, we content ourselves with the conclusion, which all the monuments impress on us, that, long before the dawn of history, there had existed in that singular region a great people, whose architectural monuments have outlasted their learning, their philosophy, and almost even their very name.

NUBIAN Desert, a vast tract of barren rocks and burning sands, extending from Syene in Upper Egypt, to Geon, the capital of Berber in Nubia. As Syene is in latitude 24. 0. 45. north, and Geon in latitude 17. 57. 22., the length of this desert from north to south is 6. 3. 23., or upwards of 420 English miles. Its breadth from east to west has not, as far as we know, been precisely ascertained.

NUCKERGAUT, a town of Northern Hindustan, in the province of Serinagur. Long. 78. 5. E. Lat. 30. 3. N.

NUCLEUS, in general, denotes the kernel of a nut, or any seed enclosed within a husk. The term *nucleus* is also used for the body of a comet, otherwise called its *head.*

NUCTA, a dew, which, falling in Egypt about St John's day, is, by the superstitious natives of the country, considered as miraculous, and the peculiar gift of that saint.

NUDDEA, a town of Bengal, and capital of a district of the same name. It is situated on an island at the confluence of the Jelinghy and Cossimbazar Rivers with the Hooghly, sixty miles north from Calcutta. It was the capital of a Hindu principality anterior to the Mogul conquest of Hindustan, and was taken and entirely destroyed in the year 1204. In modern times it has been the seat of a Brahmin seminary of learning; anterior, however, to that in Benares. Long. 88. 24. E. Lat. 23. 25. N. The district is situated between the twenty-second and twenty-fourth degrees of north latitude. It is of a sandy soil, and is considered as the healthiest and driest part of Bengal, though it is not equally productive with some others. It is computed to contain 764,000 inhabitants, about a third of whom are Mahommedans. The principal towns are Kishenagur, Nuddea, and Santipore.

NUESTRA Senhora de Luz, an island in the Pacific h Ocean, discovered by Quiros in 1506. It appears to be the same island which was called Pic de l'Etoile by Bougainville. Lat. 14. 30. S.

NULDINGAH, a town of Hindustan, in the province of Bengal, seventy-four miles north east by north from Calcutta. Long. 89. 7. E. Lat. 23. 25. N.

NUJENGODE, a town of Hindustan, in the province of Mysore, which stands on the south bank of the Cubany River, and is inhabited by Brahmins, who derive their support from a celebrated pagoda or temple, to which immense numbers of Hindus resort. Long. 76. 50. E. Lat. 12. 1. N.

NUMA Pompilius, the fourth son of Pompilius Pompo, an illustrious Sabine. Having married Tatia, the daughter of King Tatius, he remained with her in his native country, preferring the tranquillity of a private life to the splendour of a court. Upon the death of his wife, with whom he had lived thirteen years, he gave himself up entirely to the study of wisdom; and, leaving the city of Cures, confined himself to the country, wandering from solitude to solitude, in search only of those woods and fountains which religion had consecrated. His recluse life gave rise to the fable, which was very early received amongst the Sabines, that Numa lived in familiarity with the nymph Egeria. Upon the death of Romulus, both the senate and people strongly solicited him to become their king. They despatched Julius Proculus and Valerius Volesus, two senators of distinction, to acquaint Numa with their resolution, and make him an offer of the kingdom. The Sabine philosopher at first rejected their proposal; but being at last prevailed upon by the arguments and entreaties of the deputies, joined with those of his father, and of Martius his near relation, he at length yielded, and having offered sacrifices to the gods, set out for Rome, where he was received by all ranks of people with loud shouts of joy.

After a reign of forty-two years, during which he had given every possible encouragement to the useful arts, and in which he had cultivated peace, Numa died in the year of Rome 82. Not only the Romans, but also the neighbouring nations, were eager to pay respect to the memory of a monarch whom they revered for his abilities, moderation, and humanity. He forbade his body to be burned, according to the custom of the Romans, and ordered it to be buried near Mount Janiculum, along with many of the books which he had written. These books were accidentally found by one of the Romans, about four hundred years after his death; and as they contained nothing new or interesting, but merely the reasons why he had made innovations in the form of worship and in the religion of the Romans, they were burned by order of the senate.

NUMANTIA, a very noble city, the ornament of the Hither Spain, and celebrated for the long war of twenty years which it maintained against the Romans. The baseness and injustice of the Romans during this war were truly disgraceful to them, and altogether unworthy of a great and powerful people. The inhabitants obtained some advantages over the Roman forces, till Scipio Africanus was empowered to finish the war, and to effect the destruction of Numantia. He began the siege with an army of sixty thousand men, and was bravely opposed by the besieged, who were no more than four thousand men able to bear arms. Both armies behaved with uncommon valour, and the courage of the Numantines was soon changed into the fury of despair. Their provisions began to fail, and they fed upon the flesh of their horses, and afterwards upon that of their dead companions; but at last they were obliged to draw lots to kill and devour one another. The melancholy situation of their affairs obliged them to surrender to the Roman general. Scipio required them to deliver themselves up on the morrow; but they refused, and when a longer time had been granted to their petitions, they retired, and having set fire to their houses, destroyed themselves, so that not even one remained to adorn the triumph of the conqueror. Some historians, however, deny this, asserting that a number of Numantines delivered themselves into Scipio's hands, and that fifty of them were drawn in triumph at Rome, the rest being sold as slaves. The fall of Numantia was more glorious than that of Carthage or Corinth, though the place was much inferior to either. It was taken by the Romans 629 A. U. C.; and the conqueror obtained the surname of *Numanticus*.

Number.

NUMBER, an assemblage of several units, or things of the same kind. Number is either abstract or applicate; abstract, when referred to things in general, without attending to their particular properties; and applicate, when considered as the number of a particular sort of things, as yards, trees, or the like. When particular things are mentioned, there is always something more considered than barely their numbers; so that what is true of numbers in the abstract, or when nothing but the number of things is considered, will not be true when the question is limited to particular things. For instance, the number two is less than three, yet two yards is a greater quantity than three inches; and the reason is, because regard must be had to their different natures as well as number, whenever things of a different species are considered; for although we can compare the number of such things abstractedly, yet we cannot compare them in any applicate sense. And this difference is necessary to be considered, because upon it the true sense, and the possibility or impossibility, of some questions depend. Number is unlimited in respect of increase; because we can never conceive a number so great but there is still a greater. However, in respect of decrease, it is limited; unity being the first and least number, below which, therefore, it cannot descend.

Mathematicians, considering number under a great many relations, have established the following distinctions. Broken numbers are the same with fractions. Cardinal numbers are those which express the quantity of units, as 1, 2, 3, 4, &c.; whereas ordinal numbers are those which express order, as 1st, 2d, 3d, &c. Compound number is one divisible by some other number besides unity; as 12, which is divisible by 2, 3, 4, and 6. Numbers, as 12 and 15, which have some common measure besides unity, are said to be compound numbers amongst themselves. Cubic number is the product of a square number by its root; as 27, which is the product of the square number 9 by its root 3. All cubic numbers, the root of which is less than 6, being divided by 6, the remainder is the root itself. Thus $27 \div 6$ leaves the remainder 3, its root; 216, the cube of 6, being divided by 6, leaves no remainder; 343, the cube of 7, leaves a remainder 1, which, added to 6, is the cube root: and 512, the cube of 8, divided by 6, leaves a remainder 2, which, added to 6, is the cube root. Hence the remainders of the divisions of the cubes above 216, divided by 6, being added to 6, always give the root of the cube so divided till that remainder be 5, and consequently 11, the cube root of the number divided. But the cubic numbers above this being divided by 6, there remains nothing, the cube root being 12. Thus the remainders of the higher cubes are to be added to 12, and not to 6, till you come to 18, when the remainder of the division must be added to 18; and so on *in infinitum*. Determinate number is that referred to some given unit, as a ternary or three; whereas an indeterminate one is that referred to unity in general, and is called *quantity*. Homogeneal numbers are those referred to the same unit; as those referred to different units are termed *heterogeneal*. Whole numbers are otherwise called *integers*. Rational number is one commensurable with unity; as a number incommensurable with unity is termed *irrational*, or a *surd*. In the same manner, a rational whole number is that of

Number.

which unity is an aliquot part; a rational broken number, that equal to some aliquot part of unity; and a rational mixed number, that consisting of a whole number and a broken one. Even number is that which may be divided into two equal parts without any fraction, as 6, 12, &c. The sum, difference, and product, of any number of even numbers, is always an even number. An evenly even number is that which may be measured, or divided, without any remainder, by another even number, as 4 by 2; an unevenly even number, when a number may be equally divided by an uneven number, as 20 by 5; uneven number, that which exceeds an even number, at least by unity, or which cannot be divided into two equal parts, as 3, 5, &c. The sum or difference of two uneven numbers makes an even number; but the factum of two uneven ones makes an uneven number. If an even number be added to an uneven one, or if the one be subtracted from the other, in the former case the sum, in the latter the difference, is an uneven number; but the factum of an even and uneven number is even. The sum of any even number of uneven numbers is an even number; and the sum of any uneven number of uneven numbers is an uneven number.

Primitive or prime numbers are those divisible only by unity, as 5, 7, &c.; and prime numbers amongst themselves are those which have no common measure besides unity, as 12 and 19. Perfect number is that the aliquot parts of which added together make the whole number, as 6, 28; the aliquot parts of 6 being 3, 2, and 1, = 6; and those of 28, being 14, 7, 4, 2, 1, = 28. Imperfect numbers are those the aliquot parts of which added together make either more or less than the whole, and these are distinguished into abundant and defective. An instance in the former case is 12, the aliquot parts of which, 6, 4, 3, 2, 1, make 16; and in the latter case 16, the aliquot parts of which 8, 4, 2, and 1, make but 15. Plane number is that arising from the multiplication of two numbers, as 6, which is the product of 3 by 2; and these numbers are called the *sides of the plane*. Square number is the product of any number multiplied by itself; thus 4, which is the factum of 2 by 2, is a square number. An even square number added to its root makes an even number.

Figurate numbers are such as represent some geometrical figure, in relation to which they are always considered; as triangular, pentagonal, and pyramidal numbers. Figurate numbers are distinguished into orders, according to their place in the scale of their generation, being all produced one from another, viz. by adding continually the terms of any one, the successive sums are the terms of the next order, beginning from the first order, which is that of equal units, 1, 1, 1, 1, &c.; then the second order consists of the successive sums of those of the first order, forming the arithmetical progression 1, 2, 3, 4, &c.; those of the third order are the successive sums of those of the second, and are the triangular numbers 1, 3, 6, 10, 15, &c.; those of the fourth order are the successive sums of those of the third, and are the pyramidal numbers 1, 4, 10, 20, 35, &c.; and so on, as below:

Order.	Names.	Numbers.
1.	Equals,	1, 1, 1, 1, 1, &c.
2.	Arithmeticals,	1, 2, 3, 4, 5, &c.
3.	Triangulars,	1, 3, 6, 10, 15, &c.
4.	Pyramidals,	1, 4, 10, 20, 35, &c.
5.	Second Pyramidals,	1, 5, 15, 35, 70, &c.
6.	Third Pyramidals,	1, 6, 21, 56, 126, &c.
7.	Fourth Pyramidals,	1, 7, 28, 84, 210, &c.

The above are all considered as different sorts of triangular numbers, being formed from an arithmetical progression the common difference of which is 1. But if that common difference be 2, the successive sums will be the series of square numbers; if it be 3, the series will be pentagonal numbers, or pentagons; if it be 4, the series will be hexagonal numbers, or hexagons; and so on. Thus:

Arithmeticals.	First Sums, or Polygons.	Second Sums, or Second Polygons.
1, 2, 3, 4	Tri. 1, 3, 6, 10	1, 4, 10, 20
1, 3, 5, 7	Sqrs. 1, 4, 9, 16	1, 5, 14, 30
1, 4, 7, 10	Pent. 1, 5, 12, 22	1, 6, 18, 40
1, 5, 9, 13	Hex. 1, 6, 15, 28	1, 7, 22, 50
&c.		

The reason of the names, triangles, squares, pentagons, hexagons, and the like, is, that those numbers may be placed in the form of these regular figures or polygons. But the figurate numbers of any order may also be found without computing those of the preceding orders; which is done by taking the successive products of as many of the terms of the arithmeticals, 1, 2, 3, 4, 5, &c. in their natural order, as there are units in the number which denominates the order of figurates required, and dividing these products always by the first product. Thus the triangular numbers are found by dividing the products 1×2, 2×3, 3×4, 4×5, &c. each by the first product 1×2; the first pyramids by dividing the products $1 \times 2 \times 3$, $2 \times 3 \times 4$, $3 \times 4 \times 5$, &c. by the first $1 \times 2 \times 3$. And, in general, the figurate numbers of any order n, are found by substituting successively 1, 2, 3, 4, 5, &c. instead of x in this general expression $\frac{x \cdot x+1 \cdot x+2 \cdot x+3 \cdot \&c.}{1 \cdot \; 2 \; \cdot \; 3 \; \cdot \; 4 \; \cdot \&c.}$; where the factors in the numerator and denominator are supposed to be multiplied together, and to be continued till the number in each be less by 1 than that which expresses the order of the figurates required.[1]

Polygonal or polygonous numbers are the sums of arithmetical progressions beginning with unity, and these, where the common difference is 1, are called *triangular numbers*; where it is 2, *square numbers*; where it is 3, *pentagonal numbers*; where it is 4, *hexagonal numbers*; where it is 5, *heptagonal numbers*, &c. Pyramidal numbers, the sums of polygonous numbers, collected after the same manner as the polygons themselves, and not gathered out of arithmetical progressions, are called *first pyramidal numbers*; and the sums of the first pyramidals are called *second pyramidals*, &c. If they arise out of triangular numbers, they are called *triangular pyramidal numbers*; and if out of pentagons, *first pentagonal pyramidals*. From the manner of summing up polygonal numbers, it is easy to conceive how the prime pyramidal numbers are found. The formula $\frac{(a-2)\,n^3 + 3\,n^3 - (a-5)\,n}{6}$ expresses all the prime pyramidals.

The number 9 has a very curious property, its products always composing either 9 or some lesser product thereof. If our limits permitted us, we could instance in a variety of other numbers properties both curious and surprising. Such speculations are indeed by some men considered as trifling and useless. But perhaps they judge too hastily; for few employments are more innocent, none more ingenious, nor, to those who have a taste for them, more amusing.

Numbers were by the Jews, as well as the ancient Greeks

[1] See Maclaurin's Fluxions, art. 351, in the notes; also Simpson's Algebra, p. 213; or Malcolm's Arithmetic, p. 396, where the subject of figurates is treated in a very extensive and perspicuous manner. Hutton's Mathematical Dictionary may also be consulted.

and Romans, expressed by means of letters of the alphabet. Hence we may conceive how imperfect and limited their arithmetic was; because the letters could not be arranged in a series, or in different lines, conveniently enough for the purposes of ready calculation. The invention of the ciphers, or arithmetical figures, which we now make use of, has given us in this respect a very great advantage over the ancients; to say nothing of that which is derived from these figures having a value in position. See ARITHMETIC.

The letters chiefly employed by the Romans to express numbers were, M for 1000, D for 500, C for 100, L for 50, V for 5, X for 10, and I for one. M probably signifies 1000, because it is the initial of *mille;* D stands for 500, because it is *dimidium mille;* C signifies 100, as being the first letter of the word *centum;* L stands for 50, because it is the half of C, having formerly been written thus, L; V signifies 5, because V is the half of X, which stands for 10; I stands for one, because it is the first letter of *initium.* These, however, are fanciful derivations, and an explanation more accordant with philosophical principles has been given in the article ARITHMETIC. See also NUMERAL LETTERS.

The Jewish cabbalists, the Grecian conjurors, and the Roman augurs, had a great veneration for particular numbers, and the result of particular combinations of numbers. Thus three, four, six, seven, nine, ten, were full of divine mysteries, and of great efficacy.

NUMBERS, in *Poetry* and *Oratory*, are certain measures, proportions, or cadences, which render a verse, period, or song agreeable to the ear.

Poetical numbers consist in a certain harmony in the order, quantities, and adjustment of the feet and syllables which render the piece musical to the ear, and capable of being sung, for which all the verses of the ancients were intended. It is of these numbers Virgil speaks in his ninth Eclogue, when he makes Lycidas say, *Numeros memini, si verba tenerem;* meaning, that although he had forgotten the words of the verses, yet he remembered the feet and measure of which they were composed.

Rhetorical or prosaic numbers are a sort of simple unaffected harmony, less glaring than that of verse, but such as is perceived and affects the mind with pleasure.

Book of NUMBERS, the fourth book of the Pentateuch, taking its denomination from the numbering of the families of Israel. A part of this book is historical, relating to several remarkable passages in the march of the Israelites through the wilderness. It contains a distinct relation of their several movements from one place to another, or their forty-two stages through the wilderness, and many other things, by which we are instructed and confirmed in some of the most weighty truths which have immediate reference to God and his providence in the world. But the greater part of this book is occupied in enumerating those laws and ordinances, whether civil or ceremonial, which were given by God, but not mentioned before in the preceding books.

NUMERAL LETTERS are those letters of the alphabet which are generally used for figures, as I, one; V, five; X, ten; L, fifty; C, a hundred; D, five hundred; M, a thousand; and so on. It is not agreed how the Roman numerals originally received their value. It has been supposed, as we have observed in the article NUMBER, that the Romans used M to denote 1000, because it is the first letter of *mille,* which is the Latin word for 1000; and C to denote 100, because it is the first letter of *centum,* which in Latin means 100. It has also been supposed that D, being formed by dividing the old M in the middle, was therefore appointed to stand for 500, that is, half as much as the M stood for when it was whole; and that L being half a C, originally written ⊏, was for the same reason used to denominate fifty. But what reason is there to suppose that 1000 and 100 were the numbers which letters were first used to express? And what reason can be assigned why D, the first letter in the Latin word *decem,* ten, should not rather have been chosen to stand for that number than for 500, because it had a rude resemblance to half an M? But if these questions could be satisfactorily answered, there are other numeral letters which have never yet been accounted for at all. These considerations render it probable that the Romans did not, in their original intention, employ letters to express numbers at all. The most natural account of the matter seems to be this: The Romans probably put down a single stroke, I, for one, as is still the practice of those who score upon a slate or with chalk. This stroke, I, they doubled, trebled, and quadrupled, to express 2, 3, and 4; thus, II., III., IIII. So far they could easily number the strokes with a glance of the eye. But they presently found that if more were added it would soon be necessary to tell the strokes one by one. For this reason, then, when they came to 5, they expressed it by joining two strokes together in an acute angle, thus, V; which will appear the more probable, if it be considered that the progression of the Roman numbers is from 5 to 5, that is, from the fingers on one hand to the fingers on the other. Ovid has touched upon the original of this in his *Fasti* (lib. iii.), and Vitruvius has made a similar remark.

After they had made this acute angle V for five, they added the single strokes to it to the number of four, thus VI., VII., VIII., VIIII., and then, as the strokes could not be further multiplied without confusion, they doubled their acute angle by prolonging the two lines beyond their intersection, thus, X, to denote two fives, or ten. After this they doubled, trebled, and quadrupled this double acute angle thus, XX., XXX., XXXX.; they then, for the same reason which induced them first to make a single and then to double it, joined two single strokes in another form, and instead of an acute angle, made a right angle, L, to denote fifty. When this fifty was doubled, they then doubled the right angle thus, E, to denote 100; and having numbered this double right angle four times, thus, ⊏⊏, ⊏⊏⊏, ⊏⊏⊏⊏, when they came to the fifth number, as before, they reverted it, and put a single stroke before it thus I⊐, to denote 500; and when this 500 was doubled, then they also doubled their double right angle, setting two double right angles opposite to each other, with a single stroke between them, thus, ⊏I⊐, to denote 1000. When this note for 1000 had been four times repeated, then they put down I⊐⊐ for 5000, ⊏⊏I⊐⊐ for 10,000, and I⊐⊐⊐ for 50,000, and ⊏⊏⊏I⊐⊐⊐ for 100,000, I⊐⊐⊐⊐ for 500,000, and ⊏⊏⊏⊏I⊐⊐⊐⊐ for one million.

That the Romans did not originally write M for 1000, and C for 100, but square characters, as they are represented above, we are expressly informed by Paulus Manutius; but the corners of the angles being cut off by the transcribers for despatch, these figures were gradually brought into what are now numeral letters. When the corners of ⊏I⊐ were made round, it stood thus CIↃ, which is so near the Gothic *m*, that it soon deviated into that letter; so I⊐ having the corners rounded, stood thus, IↃ, and then easily deviated into D. L also became a plain C by the same means; the single rectangle which denoted fifty was, without alteration, a capital L; the double acute angle was an X; the single acute angle a V consonant; and a plain single stroke the letter I; and thus these seven letters, M, D, C, L, X, V, I, became numerals.

NUMERAL *Characters* of the Arabs are those figures which are now used in all the operations of arithmetic in every nation in Europe. See the article ARITHMETIC.

NUMERATION, or NOTATION, in *Arithmetic*, the art of expressing in characters any number proposed in words, or of expressing in words any number proposed in characters. See ARITHMETIC.

NUMERICAL, Numerous, or *Numeral*, something relating to numbers; thus Numerical Algebra is that which makes use of numbers instead of letters of the alphabet. Numerical difference is also that by which one man is distinguished from another. Hence a thing is said to be numerically the same, when it is so in the strictest sense of the word.

NUMIDIA, an ancient kingdom of Africa, bounded on the north by the Mediterranean Sea; on the south by Gætulia, or part of Libya Interior; on the west by the Mulucha, a river which separated it from Mauritania; and on the east by the Tusca, another river which formed its conterminous boundary with Africa Propria.

This country included two divisions, one inhabited by the *Massyli*, and the other by the *Massæsyli;* the country of the latter being also called in after times *Mauritania Cæsariensis*, and that of the former *Numidia Propria.* The country of the Massyli, or, as some call it, *Terra Metagonitis*, was separated from the territory of Carthage by its eastern boundary the river Tusca, and from the kingdom of the Massæsyli, or Mauritania Cæsariensis, by the river Ampsaga; and it seems to have corresponded with that part of the province of Constantina lying between the Zaine and the Wed al Kebeer, which is above 130 miles in length, and more than 100 in breadth. The sea-coast of this province is for the most part mountainous and rocky, answering to the appellation given to it by Abulfeda, who calls it *El Edwaa*, the high or lofty. It is far from being equal in extent to the ancient country of the Massæsyli, which, however, Strabo informs us, was inferior to the country of the Massyli. Its capital was Cirta, a place of very considerable note amongst the ancients.

Several learned writers have supposed that the tract extending from the isthmus of Suez to the lake Tritonis was chiefly peopled by the descendants of Mizraim, and that the posterity of his brother Put, or Phut, spread themselves all over the country between that lake and the Atlantic Ocean. And to this notion Herodotus gives some countenance; for he tells us that the Libyan Nomades, whose territories to the west were bounded by the Triton, agreed in their customs and manners with the Egyptians; but that the Africans, from that river to the Atlantic Ocean, differed from them in almost all points. Ptolemy mentions a city called *Putea*, near Adrametum, and Pliny a river of Mauritania Tingitana, known by the name of *Fut*, or *Phut;* and the district adjacent to this river was called *Regio Phutensis*, which plainly involves in it the name of *Phut.* That word signifies scattered or dispersed; and this agrees very well with what Mela and Strabo relate of the ancient Numidians; so that we may, without any scruple, admit the aborigines of this country to have been the descendants of Phut.

The history of Numidia, during many of the early ages, is buried in oblivion. It is probable, however, that as the Phœnicians were masters of a great part of the country, their transactions had been recorded, and were generally known to the Carthaginians. King Jarbas probably reigned here as well as in Africa Propria, if not in Mauritania and other parts of Libya, when Dido began to build Byrsa. It appears from Justin, that about the age of Herodotus the people of this country were called both Africans or Libyans, and Numidians. Justin likewise intimates, that about this time the Carthaginians vanquished both the Moors or Mauritanians and the Numidians; in consequence of which they were excused from paying the tribute which had hitherto been demanded of them.

After the conclusion of the first Punic war, the African troops carried on a sanguinary contest against their masters the Carthaginians; and the most active in this rebellion, according to Diodorus Siculus, were a part of the Numidian nation named Micatanians. This so incensed the Carthaginians, that after Hamilcar had either killed or taken prisoners all the mercenaries, he sent a large detachment to ravage the country of those Numidians; and the commandant of that detachment executed his orders with the utmost cruelty, plundering the district in a terrible manner, and crucifying, without distinction, all the prisoners who fell into his hands. This filled the rest with such indignation and resentment, that both they and their posterity ever afterwards cherished an implacable hatred to the Carthaginians.

In the time of the second Punic war, Syphax, king of the Massæsyli, having entered into an alliance with the Romans, gave the Carthaginians a considerable defeat. This induced Gala, king of the Massyli, to conclude a treaty with the Carthaginians, in consequence of which his son Masinissa marched at the head of a powerful army to give Syphax battle. The contest ended in favour of Masinissa; thirty thousand of the Massæsyli were put to the sword, and Syphax driven into Mauritania; and a similar reverse attended Syphax in another engagement, where his troops were entirely defeated and dispersed.

Gala having died whilst his son Masinissa was acting at the head of the Numidian troops sent to the assistance of the Carthaginians in Spain, his brother Desalces, according to the established rules of succession in Numidia, took possession of the Massylian throne. That prince, however, died soon after his succession, and Capusa his eldest son succeeded him. But he did not long enjoy his high dignity; for one Mezetulus, a person of the royal blood, but an enemy to the family of Gala, found means to excite a great part of his subjects to revolt. A battle soon took place between him and Capusa, in which the latter was slain with many of the nobility, and his army entirely defeated. But though Mezetulus thus became possessed of the sovereignty, he did not think proper to assume the title of king, and only styled himself guardian to Lacumaces, the surviving son of Desalces, whom he graced with the royal title. To support himself in his usurpation, he married the widow of Desalces, who was Hannibal's niece, and consequently of the most powerful family in Carthage; and in order to attain the same end, he sent ambassadors to Syphax, to conclude a treaty of alliance with him. In the mean time, Masinissa, having received advice of his uncle's death, of his cousin's slaughter, and of Mezetulus's usurpation, immediately passed over to Africa, and went to the court of Bocchar king of Mauritania to solicit succours. Bocchar, sensible of the great injustice which had been done Masinissa, gave him a body of four thousand Moors to escort him to his dominions; and his subjects, being apprised of his approach, joined him upon the frontiers with a party of five hundred men. The Moors, in pursuance of their orders, returned home as soon as Masinissa reached the confines of his kingdom; notwithstanding which, and the small body that declared for him, having accidentally met Lacumaces at Thapsus, with an escort, going to implore the assistance of Syphax, he drove him into the town, which he carried by assault after a faint resistance. Lacumaces, however, with many of his men, found means to escape to Syphax. The fame of this exploit gained Masinissa great credit, insomuch that the Numidians flocked to him from all parts, and amongst the rest many of his father Gala's veterans, who pressed him to make a speedy and vigorous effort to recover his hereditary dominions. Lacumaces having joined Mezetulus with a reinforcement of Massæsylians, which he had prevailed upon Syphax to send to the assistance of his ally, the usurper advanced at the head of a numerous army to offer Masinissa battle, which that prince, although much inferior in numbers, did not decline. An engagement accordingly ensued, and, notwithstanding the inequality of numbers, it ended in the defeat of Lacumaces. The immediate consequence of this victory of Masinissa was the quiet and peaceable possession of his kingdom; Mezetulus and Lacumaces, with a few that attended them, having fled into the territories of Carthage. However, being apprehensive that he should be obliged to sustain a war against Syphax, he offered to treat Lacumaces with as many marks of distinction as his father Gala had Desalces, provided that prince would put himself under his protection. He also promised Mezetulus pardon, and the restitution of all the property forfeited by his treasonable conduct, if he would make his submission to him. Both of them readily complied with the proposal, and immediately returned home; so that the tranquillity and repose of Numidia would have been settled upon a solid and lasting foundation, had not this been prevented by Asdrubal, who was then at the court of Syphax. He insinuated to that prince, who was disposed to live amicably with his neighbours, "that he was greatly mistaken if he imagined Masinissa would be satisfied with his hereditary dominions; that he was a prince of much greater capacity and ambition than either his father Gala, his uncle Desalces, or any of his family; that he had discovered in Spain marks of rare and uncommon merit; and that, in fine, unless this rising flame was extinguished before it came to too great a head, both the Massæsylian and Carthaginian states would infallibly be consumed by it." Syphax, alarmed by these suggestions, advanced with a numerous body of forces into a district which had long been a subject of dispute between him and Gala, but was then in possession of Masinissa. This brought on a general action between these two princes, wherein the latter was totally defeated, his army dispersed, and he himself obliged to fly to the top of Mount Balbus, attended by only a few of his horse. Such a decisive battle, before Masinissa had been firmly seated on his throne, could not fail to put Syphax into possession of the kingdom of the Massyli. Masinissa, in the mean time, made nocturnal incursions from his post upon Mount Balbus, and plundered all the adjacent country, particularly that part of the Carthaginian territory contiguous to Numidia. This district he not only thoroughly pillaged, but likewise laid waste with fire and sword, carrying off from thence an immense booty, which was purchased of him by some merchants, who had put into one of the Carthaginian ports for that purpose. In fine, he did the Carthaginians more damage, not only by committing such dreadful devastations, but by massacring and carrying into captivity vast numbers of their subjects on this occasion, than they could have sustained in a pitched battle, or a whole campaign of a regular war. Syphax, at the pressing and reiterated instances of the Carthaginians, sent Bocchar, one of his most active commanders, with a detachment of four thousand foot and two thousand horse, to reduce this pestilent gang of robbers; promising him a great reward if he would bring Masinissa either alive or dead. Bocchar, having watched an opportunity, surprised the Massylians as they were straggling about the country without any order or discipline; so that he took many prisoners, dispersed the rest, and pursued Masinissa himself, with a few of his men, to the top of the mountain where he had before taken post. Considering the expedition as ended, he not only sent many head of cattle, and the other booty that had fallen into his hands, to Syphax, but likewise all the force, except five hundred foot and two hundred horse. With this detachment he drove Masinissa from the summit of the hill, and pursued him through several narrow passes and defiles as far as the plains of Clupea, where he so completely surrounded him, that all the Massylians except four were put to the sword, and Masinissa himself, after having received a dangerous wound, escaped with the utmost difficulty. As this was effected by crossing a rapid river, in which attempt two of his four attendants perished in the sight of the detachment that pursued him, it was rumoured all over Africa that Masinissa also was drowned; news which gave inexpressible pleasure to Syphax and the Carthaginians. For some time he lived undiscovered in a cave, where he was supported by the robberies of the two horsemen who had made their escape with him. But having cured his wound by the application of some medicinal herbs, he began to advance boldly towards his own frontiers, giving out publicly that he intended once more to take possession of his kingdom. In his march he was joined by about forty horse, and, soon after his arrival amongst the Massyli, so many people flocked to him from all parts, that out of them he formed an army of six thousand foot and four thousand horse. At the head of these forces he not only reinstated himself in possession of his dominions, but likewise laid waste the borders of the Massæsyli. This so irritated Syphax, that he immediately assembled a numerous body of troops, and encamped very commodiously upon a ridge of mountains between Cirta and Hippo. His army he commanded in person, and detached his son Vermina, with a considerable force, to make a detour, and attack the enemy in the rear. In pursuance of his orders, Vermina set out in the beginning of the night, and took post in the place appointed, without having been discovered by the enemy. In the mean time Syphax decamped, and advanced towards the Massyli, in order to give them battle. When he had possessed himself of a rising ground which led to their camp, and concluded that his son Vermina must have formed the ambuscade behind them, he began the fight. Masinissa being advantageously posted, and his soldiers distinguishing themselves in an extraordinary manner, the dispute proved long and bloody. But Vermina having unexpectedly fallen upon their rear, and by this means obliged them to divide their forces, which were scarcely able before to oppose the main body under Syphax, they were soon thrown into confusion, and forced to betake themselves to a precipitate flight. All the avenues being blocked up, partly by Syphax, and partly by his son, such a dreadful slaughter was made of the unhappy Massylians, that only Masinissa himself, and sixty horse, escaped to the Lesser Syrtis. Here he remained, between the confines of the Carthaginians and the Garamantes, till the arrival of Lælius and the Roman fleet on the coast of Africa.

By the assistance of Lælius, Masinissa at last reduced Syphax's kingdom. According to Zonaras, Masinissa and Scipio, before the memorable battle of Zama, deprived Hannibal, by a stratagem, of some advantageous posts; which, with a solar eclipse that happened during the heat of the action, and not a little intimidated the Carthaginian troops, greatly contributed to the victory obtained by the Romans. At the conclusion, therefore, of the second Punic war, he was amply rewarded by the Romans for the important services he had rendered them. As for Syphax, after the loss of his dominions, he was kept in confinement for some time at Alba; but being removed thence in order to grace Scipio's triumph, he died at Tibur, in his way to Rome. Zonaras adds, that his corpse was decently interred; that all the Numidian prisoners were released; and that Vermina, by the assistance of the Romans, took peaceable possession of his father's throne. However, part of the Massæsylian kingdom had before been annexed to Masinissa's dominions, in order to reward that prince for his singular fidelity and firm attachment to the Romans.

Nothing further is requisite to complete the history of this famous prince, than to exhibit some points of his conduct towards the decline and at the close of life; the wise dispositions made after his death by Æmilianus for the regulation of his domestic affairs; and some particulars relating to his character, genius, and habit of body, drawn from the most celebrated Greek and Roman authors.

By drawing a line of circumvallation around the Cartha-

Numidia. ginian army under Asdrubal, posted upon an eminence, Masinissa cut off all manner of supplies, and thus introduced both the plague and famine into their camp. As the body of Numidian troops employed in this blockade was not nearly so numerous as the Carthaginian forces, it is evident, that the line here mentioned must have been extremely strong, and consequently the effect of great labour and art. The Carthaginians, finding themselves reduced to the last extremity, concluded a peace upon the terms which Masinissa himself dictated to them, viz. That they should deliver up all deserters; that they should recall their exiles, who had taken refuge in his dominions; that they should pay him five thousand talents of silver within the space of fifty years; and that their soldiers should pass under the yoke, each of them carrying off only a single garment. As Masinissa himself, though between eighty and ninety years of age, conducted the whole enterprise, he must have been extremely well versed in fortification, and other branches of the military art; and he must likewise have retained his understanding to the last. This happened a short time before the commencement of the third Punic war.

Soon afterwards, the consuls landed an army in Africa, in order to lay siege to Carthage, without imparting their design to Masinissa. This not a little chagrined him, as it was contrary to the former practice of the Romans, who, in the preceding war, had communicated their intentions to him, and consulted him on all occasions. When, therefore, the consuls applied to him for a body of his troops to act in concert with their forces, he answered, "That they should have a reinforcement from him when they stood in need of it." The reflection, that after he had extremely weakened the Carthaginians, and even brought them to the brink of ruin, his pretended friends should come to reap the fruits of his victory, without giving him the least intelligence of their design, must have been sufficiently galling to an old and faithful ally, who had done and suffered so much in their cause.

However, his mind soon returned to its natural bias, which was in favour of the Romans. Finding his end approaching, he sent to Æmilianus, then a tribune in the Roman army, to desire a visit from him. What he proposed by this visit, was to invest him with full powers to dispose of his kingdom and estate as he should think proper, for the benefit of his children. The high idea he had entertained of that young hero's abilities and integrity, together with his gratitude and affection for the family into which he was adopted, induced him to take this step. But believing that death would not permit him to have a personal conference with Æmilianus upon this subject, he informed his wife and children, in his last moments, that he had empowered him to dispose, in an absolute manner, of all his possessions, and divide his kingdom amongst his sons; to which he subjoined, "I require, that whatever Æmilianus may decree, shall be executed as punctually as if I myself had appointed it by my will." Having uttered these words, he expired, at a very advanced age.

Masinissa, before his death, gave his ring to his eldest son Micipsa, but left the distribution of all his other effects and possessions amongst his children entirely to Æmilianus. Of fifty-four sons who survived him, only three were legitimate, to wit, Micipsa, Gulussa, and Mastanabal. Æmilianus arrived at Cirta after he had expired, and divided his kingdom, or rather the government of it, amongst these three, though to the others he gave considerable possessions. To Micipsa, who was a prince of a pacific disposition, and the eldest son, he assigned Cirta, the metropolis, for the place of his residence, in exclusion of the others. Gulussa, the next to him, being a prince of military genius, had the command of the army, and the transacting of all affairs relating to peace or war, committed to his care. And Mastanabal, the youngest, had allotted him the administration of justice, an employment suitable to his education. They enjoyed in common the immense treasures Masinissa had amassed, and were all of them dignified by Æmilianus with the royal title. After he had made these various dispositions, he departed from Cirta, taking with him a body of Numidian troops, under the conduct of Gulussa, to reinforce the Roman army which was then acting against the Carthaginians.

Mastanabal and Gulussa died soon after their father, as appears from the express testimony of Sallust; and we find nothing remarkable of these princes, besides what has been already related, except that the latter continued to assist the Romans in the third Punic war, and that the former was pretty well versed in the Greek language. Micipsa, therefore, became sole possessor of the kingdom of Numidia. In his reign, and under the consulate of M. Platius Hypsæus and M. Fulvius Flaccus, according to Orosius, a great part of Africa was covered with locusts, which destroyed all the produce of the earth, and even devoured dry wood. But at last they were all carried by the wind into the African Sea, out of which being thrown in vast heaps upon the shore, a plague ensued, which swept away an infinite number of animals of all kinds. In Numidia alone eight hundred thousand men perished, and in Africa Propria two hundred thousand, including thirty thousand Roman soldiers quartered in and about Utica for the defence of the province. At Utica, in particular, the mortality raged to such a degree, that fifteen hundred dead bodies were carried out at one gate in a day. Micipsa had two sons, Adherbal and Hiempsal, whom he educated in his palace, together with his nephew Jugurtha. That young prince was the son of Mastanabal; but his mother having been only a concubine, Masinissa had taken no great notice of him. However, Micipsa considering him as a prince of the blood, took as much care of him as he did of his own children.

Jugurtha possessed several eminent qualities, which gained him universal esteem. He was very handsome, endowed with great strength of body, and adorned with the finest intellectual endowments. He did not devote himself, as young men commonly do, to a life of luxury and pleasure. He used to exercise himself, with persons of his own age, in running, riding, hurling the javelin, and other manly exercises, suited to the martial genius of the Numidians; and although he surpassed all his fellow sportsmen, there was not one of them but loved him. The chase was his only delight; but it was that of lions and other savage beasts. Sallust, to finish the picture of his character, tells us, that he excelled in all things, and spoke very little of himself.

So conspicuous an assemblage of fine talents and perfections at first charmed Micipsa, who thought them an ornament to his kingdom. However, he soon began to reflect that he was considerably advanced in years, and his children in their infancy; that mankind naturally thirsted after power, and that nothing was capable of making men run greater lengths than a vicious and unlimited ambition. These reflections soon excited his jealousy, and determined him to expose Jugurtha to a variety of dangers, some of which, he hoped, might prove fatal to the aspiring youth. With this view he gave Jugurtha the command of a body of forces which he sent to assist the Romans, who were at that time besieging Numantia in Spain. But Jugurtha, by his admirable conduct, not only escaped all those dangers, but likewise won the esteem of the whole army, and the friendship of Scipio, who sent a high character of him to his uncle Micipsa. However, that general gave him some prudent advice in relation to his future conduct; observing in him, no doubt, certain sparks of ambition, which, if lighted into a flame, he apprehended might one day be productive of the most fatal consequences.

Before this last expedition, Micipsa had endeavoured to find out some method of taking him off privately; but the popularity of Jugurtha amongst the Numidians obliged that prince to lay aside all thoughts of this kind. After his return from Spain the whole nation almost adored him. The heroic bravery he had shown there; his undaunted courage, joined to the utmost calmness of mind, which enabled him to preserve a just medium between a timorous foresight and an impetuous rashness, a circumstance rarely to be met with in persons of his age; and, above all, the advantageous testimonials of his conduct given by Scipio, attracted universal esteem. Nay, Micipsa himself, charmed with the high opinion which the Roman general had entertained of his merit, changed his behaviour towards him; resolving, if possible, to win his affection by kindness. He therefore adopted him, and declared him joint heir with his two sons to the crown. Some few years afterwards, finding that his end approached, he sent for all the three to his bed side, where, in the presence of the whole court, he desired Jugurtha to recollect with what extreme tenderness he had treated him, and consequently to consider how well he had deserved at his hands. He then entreated him to protect on all occasions his children, who, being before related to him by the ties of blood, were now by their father's bounty become his brethren. In order to fix him the more firmly in their interest, he likewise complimented him upon his bravery, address, and consummate prudence. He further insinuated, that neither arms nor treasures constitute the strength of a kingdom; but friends, who are neither won by arms nor gold, but by real services and an inviolable fidelity. "Now," continued he, "where can we find better friends than in brothers? And how can that man who becomes an enemy to his relations repose any confidence in or place dependence on strangers?" Then addressing himself to Adherbal and Hiempsal, "And you," said he, "I enjoin to pay always the highest reverence to Jugurtha. Endeavour to imitate, and if possible surpass, his exalted merit, that the world may not hereafter observe Micipsa's adopted son to have reflected greater glory upon his memory than his own children." Soon afterwards, Micipsa, who, according to Diodorus, was a prince of an amiable character, expired. Though Jugurtha did not believe that the king spoke his real sentiments in regard to him, yet he seemed extremely pleased with so gracious a speech, and made him an answer suitable to the occasion. However, that prince at the same time determined within himself to put in execution the scheme he had formed at the siege of Numantia, and which had been suggested to him by some factious and abandoned Roman officers, with whom he there contracted an acquaintance. The purport of this scheme was, that he should extort the crown by force from his two cousins, as soon as their father's eyes were closed; which, they insinuated, might easily be effected by means of his own valour, and the venality of the Romans. Accordingly, a short time after the old king's death, he found means to assassinate Hiempsal in the city of Thirmida, where his treasures were deposited, and to drive Adherbal out of his dominions. That unhappy prince found himself obliged to fly to Rome, where he endeavoured to engage the conscript fathers to espouse his quarrel; but, notwithstanding the evident justice of his cause, they had not virtue enough effectually to support him. Jugurtha's ambassadors, by distributing vast sums of money amongst the senators, brought them so far over that a majority palliated his inhuman proceedings. This encouraged the usurper's ministers to declare that Hiempsal had been killed by the Numidians on account of his excessive cruelty; that Adherbal was the aggressor in the late troubles; and that he was only chagrined because he could not make that havock amongst his countrymen which he would willingly have done. They therefore entreated the senate to form a judgment of Jugurtha's behaviour in Africa from his conduct at Numantia, rather than from the suggestions of his enemies; upon which, by far the greater part of the senate discovered that they were prejudiced in his favour. A few, however, who were not lost to honour nor abandoned to corruption, insisted upon bringing him to condign punishment. But as they could not prevail, Jugurtha had the best part of Numidia allotted him, and Adherbal was forced to rest satisfied with the other.

Jugurtha, finding now by experience that every thing was venal at Rome, as his friends at Numantia had before informed him, thought he might pursue his towering projects without meeting any obstruction from that quarter. He, therefore, immediately after the final division of Micipsa's dominions, threw off the mask, and attacked his cousin by open force. As Adherbal was a prince of a pacific disposition, and almost in all respects the reverse of Jugurtha, he was by no means a match for him. The latter therefore pillaged the territories of the former, stormed several of his fortresses, and overran a good part of his kingdom, without opposition. Adherbal, depending upon the friendship of the Romans, which his father in his last moments had assured him would be a stronger support to him than all the troops and treasures in the universe, despatched deputies to Rome to complain of these hostilities. But whilst he lost valuable time in sending thither fruitless deputations, Jugurtha overthrew him in a pitched battle, and soon afterwards shut him up in Cirta. During the siege of this city, a Roman commission arrived there, in order to persuade both parties to come to an accommodation; but finding Jugurtha untractable, the commissioners returned home without so much as conferring with Adherbal. A second deputation, composed of senators of the highest distinction, with Æmilius Scaurus, president of the senate, at their head, landed some time afterwards at Utica, and summoned Jugurtha to appear before them. That prince at first seemed to be under dreadful apprehensions, especially as Scaurus reproached him with his enormous crimes, and threatened him with the resentment of the Romans if he did not immediately raise the siege of Cirta. However, the Numidian, by his address, and the irresistible power of gold, as was afterwards suspected at Rome, so mollified Scaurus that he left Adherbal at his mercy. In fine, Jugurtha had Cirta at last surrendered to him, upon the condition only that he should spare the life of Adherbal. But the merciless tyrant, in violation of the laws of nature and humanity as well as the capitulation, when he had got possession of the town, ordered him to be put to a most cruel death. The merchants, likewise, and all the Numidians in the place capable of bearing arms, he caused to be put to the sword without distinction.

Every person at Rome inspired with any sentiment of humanity was stricken with horror at the news of this tragical event. However, all the venal senators still concurred with Jugurtha's ministers in palliating his enormous crimes; notwithstanding which, the people, excited thereto by Caius Memmius their tribune, who bitterly inveighed against the venality of the senate, resolved not to let so flagrant an instance of villany go unpunished. This disposition in them induced the conscript fathers likewise to declare their intention to chastise Jugurtha. For this purpose, an army was levied to invade Numidia, and the command of it given to the consul Calpurnius Bestia, a person of good abilities, but rendered unfit for the expedition he was to be employed on by his insatiable avarice. Jugurtha being informed of the great preparations making at Rome to attack his dominions, sent his son thither in hopes of averting the impending storm. The young prince was plentifully supplied with money, which he had orders to distribute liberally amongst the leading men. But Bestia, proposing to himself great advantages from an invasion of Nu-

Numidia. midia, defeated all his intrigues, and got a decree passed, ordering him and his attendants to leave Italy in ten days, unless they were come to deliver up the king himself, and all his territories, to the republic, by way of surrender; which decree being notified to them, they returned without so much as having entered the gates of Rome, and the consul soon afterwards landed with a powerful army in Africa. For some time he carried on the war there very briskly, and having reduced several strongholds, took many Numidians prisoners. But upon the arrival of Scaurus, a peace was granted to Jugurtha upon advantageous terms. That prince having come from Vacca, the place of his residence, to the Roman camp, in order to confer with Bestia and Scaurus, the preliminaries of the treaty were immediately after settled between them in private conferences; and every body at Rome was convinced that the prince of the senate and the consul had sacrificed the republic to their avarice. The indignation of the people, therefore, displayed itself in the strongest manner. Memmius also fired them with his speeches; and it was consequently resolved to despatch the prætor Cassius, a person they could confide in, to Numidia, to prevail upon Jugurtha to come to Rome, that they might learn from the king himself which of their generals and senators had been seduced by the pestilent influence of corruption. Upon his arrival there, Jugurtha found means to bribe one Bæbius Salca, a man of great authority amongst the plebeians, but of insatiable avarice, by whose assistance he escaped with impunity. Nay, by the efficacy of gold, he not only eluded all the endeavours of the people of Rome to bring him to justice, but likewise enabled Bomilcar, one of his attendants, to get Massiva, an illegitimate son of Micipsa, assassinated in the streets of Rome. That young prince was advised by many Romans of probity, wellwishers to the family of Masinissa, to apply for the kingdom of Numidia; which having come to the ears of Jugurtha, he prevented the application by this execrable step. However, he was obliged to leave Italy immediately.

Jugurtha had scarcely set foot in Africa, when he received advice that the senate had annulled the shameful peace concluded with him by Bestia and Scaurus. Soon afterwards, the consul Albinus transported a Roman army into Numidia, flattering himself with the hopes of reducing Jugurtha to reason before the expiration of his consulate. In this, however, he found himself deceived; for that crafty prince, by various artifices, so amused and imposed upon Albinus, that nothing of moment happened in that campaign. This rendered him strongly suspected of having betrayed his country, after the example of his predecessors. His brother Aulus, who succeeded him in the command of the army, was still more unsuccessful; for after raising the siege of Suthul, where the king's treasures were deposited, he marched his forces into a defile, out of which he found it impossible to extricate himself. He was therefore obliged to submit to the ignominious ceremony of passing under the yoke, with all his men, and to quit Numidia entirely in ten days' time, in order to deliver his troops from immediate destruction. The avaricious disposition of the Roman commander had prompted him to besiege Suthul, the possession of which place, he imagined, would make him master of all the wealth of Jugurtha, and consequently paved the way to the scandalous convention just mentioned. However, this was declared void as soon as known at Rome, from being concluded without the authority of the people. The Roman troops retired into Africa Propria, which they had now reduced into the form of a Roman province, and there took up their winter quarters.

In the mean time Caius Mamillius Limetanus, a tribune of the people, excited the plebeians to inquire into the conduct of those persons by whose assistance Jugurtha had found means to elude all the decrees of the senate. This threw the body of the people into a great ferment, and occasioned a prosecution of the guilty senators, which was carried on, for some time, with the utmost heat and violence. Lucius Metellus, the consul, during these transactions, had Numidia assigned him as his province, and consequently was appointed general of the army destined to act against Jugurtha. As he perfectly disregarded wealth, the Numidian found him superior to all his temptations; and to this contempt of money he joined all the other virtues which constitute the great captain, so that Jugurtha found him in all respects inaccessible. That prince, therefore, was now forced to regulate his conduct with the greatest caution, according to the motions of Metellus; and to exert his utmost bravery, in order to compensate for that expedient, hitherto so favourable, which now began to fail him. Marius, Metellus's lieutenant, being likewise a person of uncommon merit, the Romans reduced Vacca, a large and opulent city, and the most celebrated mart in Numidia. They also defeated Jugurtha in a pitched battle; overthrew Bomilcar, one of his generals, upon the banks of the Muthullus; and, in fine, forced the Numidian monarch to take shelter in a place rendered almost inaccessible by the rocks and woods with which it was covered. However, Jugurtha signalized himself in a surprising manner, exhibiting all that could be expected from the courage, abilities, and attention of a consummate general, to whom despair administers fresh strength, and suggests new resources. But his troops could not make head against the Romans, and were again worsted by Marius, though they obliged Metellus to raise the siege of Zama. Jugurtha, therefore, finding his country everywhere ravaged, his most opulent cities plundered, his fortresses reduced, his towns burned, and vast numbers of his subjects put to the sword and taken prisoners, began to think seriously of coming to an accommodation with the Romans. His favourite, Bomilcar, in whom he reposed the highest confidence, but who had been gained over to the enemy by Metellus, observing this disposition, found it no difficult matter to persuade him to deliver up his elephants, money, arms, horses, and deserters, in whom the main strength of his army consisted, into the hands of the Romans. Some of these last, in order to avoid the punishment due to their crime, retired to Bocchus, king of Mauritania, and enlisted into his service. But Metellus, having ordered him to repair to Tisidium, a city of Numidia, there to receive farther directions, Jugurtha refused to comply with that order, and hostilities were renewed with greater fury than ever. Fortune now seemed to declare in favour of Jugurtha, who retook Vacca, and massacred all the Roman garrison, except Turpilius the commandant. However, a Roman legion soon afterwards retook the place, and treated the inhabitants with the utmost severity. About this time, one of Mastanabal's sons, named Gauda, whom Micipsa in his will had appointed to succeed to the crown in case his two legitimate sons and Jugurtha died without issue, wrote to the senate in favour of Marius, who was then endeavouring to supplant Metellus. That prince having his understanding impaired by a declining state of health, fell a more easy prey to the base and infamous adulation of Marius. The Roman, soothing his vanity, assured him, that as he was the next heir to the crown, he might depend upon being fixed upon the Numidian throne as soon as Jugurtha was either killed or taken; and that this must in a short time happen, when once he appeared at the head of the Roman army with an unlimited commission. Soon afterwards, Bomilcar and Nabdalsa formed a design to assassinate Jugurtha, at the instigation of Metellus; but this being detected, Bomilcar and most of his accomplices suffered death. The plot, however, had such an effect upon Jugurtha, that he afterwards enjoyed no tranquillity or repose. He suspected persons of all denominations, Numidians as well as foreigners, of some black designs against him; and perpetual terror sat brooding over his mind, insomuch that he never slept except by stealth, and often changed his bed in a low plebeian manner. Starting from his sleep, he would frequently snatch his sword, and break out into the most doleful cries; so strongly was he haunted by a spirit of fear, jealousy, and distraction.

Jugurtha having destroyed great numbers of his friends on suspicion of their having been concerned in this conspiracy, and many more of them having deserted to the Romans and Bocchus king of Mauritania, he found himself, in a manner, destitute of counsellors, generals, and all persons capable of assisting him in carrying on the war. This threw him into a deep melancholy, which rendered him dissatisfied with every thing, and made him fatigue his troops with a variety of contradictory movements. Sometimes he would advance with great rapidity against the enemy, and at others retreat from them with no small celerity. Then he resumed his former courage, but soon afterwards despaired either of the valour or fidelity of the forces under his command. All his movements, therefore, proved unsuccessful, and at last he was forced by Metellus to accept battle. That part of the Numidian army which Jugurtha commanded behaved with some resolution, but the other fled at the first onset. The Romans, therefore, entirely defeated them, took all their standards, and made some prisoners. But few of them were slain in the action, since, as Sallust observes, the Numidians trusted more to their heels than to their arms for safety in this engagement.

Metellus pursued Jugurtha and his fugitives to Thala. His march to this place being through vast deserts, was extremely tedious and difficult; but being supplied with leathern bottles and wooden vessels of all sizes taken from the huts of the Numidians, which were filled with water brought by the natives who had submitted to him, he advanced towards the city. He had no sooner begun his march, than a most copious shower of rain, a thing very uncommon in these deserts, proved a great and seasonable refreshment to his troops; and this so animated them, that upon their arrival before Thala, they attacked the town with such vigour, that Jugurtha, with his family, and the treasures deposited therein, thought proper to abandon the place. After a brave defence, it was reduced; the garrison, consisting of Roman deserters, setting fire to the king's palace, and consuming themselves, together with every thing valuable to them, in the flames. Jugurtha, being now reduced to great extremities, retired into Gætulia, whence, having formed a considerable corps, he advanced to the confines of Mauritania, and engaged Bocchus, king of that country, who had married his daughter, to enter into an alliance with him; and having reinforced his Gætulian troops with a powerful body of Mauritanians, he turned the tables upon Metellus, and obliged him to keep close within his intrenchments. Sallust informs us, that Jugurtha bribed Bocchus's ministers, in order to influence that prince in his favour; and having obtained an audience, he insinuated that, should Numidia be subdued, Mauritania must be involved in its ruin, especially as the Romans seemed to have vowed the destruction of all the thrones in the universe. In support of what he advanced, he produced several instances very apposite to the point in view. However, the same author seems to intimate, that Bocchus was determined to assist Jugurtha against his enemies by the slight which the Romans had formerly shown him. That prince, at the first breaking out of the war, had sent ambassadors to Rome, to propose an offensive and defensive alliance to the republic, which, though of the utmost consequence at that juncture, a few of the most venal and infamous senators, who were abandoned to corruption, prevented from taking effect. This undoubtedly wrought more powerfully upon Bocchus in favour of Jugurtha than the relation in which he stood to him; for both the Moors and Numidians adapted the number of their wives to their circumstances, so that some of them had ten, twenty, or more. Their kings, therefore, were unlimited in this particular, and of course all degrees of affinity resulting from marriage had but little force. It is observable, that amongst the posterity of those ancient nations the same custom prevails at this day.

Such was the situation of affairs in Numidia, when Metellus received advice of the promotion of Marius to the consulate. But, notwithstanding this injurious treatment, he generously endeavoured to draw off Bocchus from Jugurtha, although this would facilitate the reduction of Numidia for his rival. To this end ambassadors were despatched to the Mauritanian court, who intimated to Bocchus, "that it would be highly imprudent to come to a rupture with the Romans without any cause at all; and that he had now a fine opportunity of concluding a most advantageous treaty with them, which was much preferable to a war." To this they added, "that whatever dependence he might place upon his riches, he ought not to run the hazard of losing his dominions by embroiling himself with other states, when he could easily avoid doing so; that it was much easier to begin a war than to end it, which it was in the power of the victor alone to do; that, in fine, he would by no means consult the interest of his subjects if he followed the desperate fortunes of Jugurtha." To this Bocchus replied, "that for his part there was nothing he wished for more than peace, but that he could not help pitying the deplorable condition of Jugurtha; that if the Romans, therefore, would grant to that unfortunate prince the same terms which they had offered him, he would bring about an accommodation." Metellus let the Mauritanian monarch know, that it was not in his power to comply with what he desired; but he nevertheless took care to keep up a private negotiation with him till the arrival of the new consul Marius. By this conduct he gained two important objects. First, he prevented Bocchus from coming to a general action with his troops; which was the very thing Jugurtha desired, hoping that this, whatever the event might be, would render a reconciliation between him and the Romans impracticable. Secondly, this inaction enabled him to discover something of the genius and disposition of the Moors, a nation of whom the Romans, till then, had scarcely formed any idea; and this, he imagined, might be of no small service, either to himself or his successors, in the future prosecution of the war.

Jugurtha, being informed that Marius, with a numerous army, had landed at Utica, advised Bocchus to retire, with part of the troops, to some place of difficult access, whilst he himself took post upon another inaccessible spot with the remaining corps. By this measure, he hoped the Romans would be obliged to divide their forces, and consequently be more exposed to his efforts and attacks. He likewise imagined, that seeing no formidable body appear, they would believe that the enemy were not in a condition to make head against them; which might occasion a relaxation of discipline, the usual attendant of too great security, and consequently produce some good effect. However, he was disappointed in both these views. For Marius, so far from suffering a relaxation of discipline to take place, trained up his troops, which consisted chiefly of new levies, in so perfect a manner, that they were soon equal in efficiency to any consular army that ever appeared in the field. He also cut off great numbers of the Gætulian marauders, defeated many of Jugurtha's parties, and had well nigh captured that prince himself near the city of Cirta. These advantages, though not of any great importance, intimidated Bocchus, who now made overtures for an accom-

Numidia. modation; but the Romans, not being sufficiently satisfied of his sincerity, paid no great attention to them. In the mean time Marius pushed on his conquests, and having reduced several places of less note, at last resolved to besiege Capsa. That this enterprise might be conducted with the greater secrecy, he suffered not the least hint of his design to transpire, even amongst any of his officers. On the contrary, in order to blind them, he detached A. Manlius, one of his lieutenants, with some light-armed cohorts, to the city of Lares, where he had fixed his principal magazine, and deposited the military chest. Before Manlius left the camp, that he might the more effectually amuse him, he intimated, that he himself with the army would take the same route in a few days; but instead of that, he bent his march towards the Tanais, and in six days' time arrived upon the banks of that river. Here he pitched his tents for a short time, in order to refresh his troops; after which he advanced to Capsa, and made himself master of the place. As the situation of this city rendered it extremely commodious to Jugurtha, whose plan of operations, ever since the commencement of the war, it had exceedingly favoured, Marius levelled it with the ground after it had been delivered up to the soldiers to be plundered. The citizens, likewise, being more strongly attached to that prince than any of the other Numidians, on account of the extraordinary privileges he indulged them with, and of course bearing a more implacable hatred to the Romans, he put to the sword or sold for slaves. The true motive of the consul's conduct on this occasion seems to have been that assigned; though we are told by Sallust, in conformity to the Roman genius, that neither avarice nor resentment prompted him to so barbarous an action, but only a desire to strike terror into the Numidians.

The Numidians, ever after this exploit, dreaded the very name of Marius; who now, in his own opinion, had eclipsed the glory of all the great achievements of his predecessor, particularly the reduction of Thala, a city in strength and situation nearly resembling Capsa. Following up this blow, he gradually presented himself before most of the places of strength in the enemy's country, many of which either opened their gates or were abandoned at his approach, being terrified at what had happened to the unfortunate citizens of Capsa. Others taken by force he laid in ashes, and, in short, filled the greatest part of Numidia with blood, horror, and confusion. Then, after an obstinate defence, he reduced a castle which seemed impregnable, being situated not far from Mulucha, where Jugurtha kept part of his treasures. In the mean time, Jugurtha not being able to prevail upon Bocchus, by his repeated solicitations, to advance into Numidia, where he found himself greatly pressed, was obliged to have recourse to his usual method of bribing the Mauritanian ministers, in order to put that prince in motion. He also promised him a third part of his kingdom, provided they could either drive the Romans out of Africa, or get all the Numidian dominions confirmed to him by treaty.

So considerable a cession could scarcely fail to engage Bocchus to support Jugurtha with his whole power. The two African monarchs, therefore, having joined their forces, surprised Marius near Cirta as he was going into winter quarters. The Roman general was so hard pushed on this occasion, that the barbarians thought themselves certain of victory, and doubted not but they should be able to extinguish the Roman name in Numidia. But their want of caution, and too great security, enabled Marius to inflict on them a total defeat; which was followed four days afterwards by so complete an overthrow, that their numerous army, consisting of ninety thousand men, by the accession of a powerful corps of Moors, commanded by Bocchus's son Volux, was entirely ruined. Sylla, the lieutenant of Marius, most eminently distinguished himself in the last action, which laid the foundation of his future greatness. Bocchus, now looking upon Jugurtha's condition as desperate, and not being willing to run the risk of losing his dominions, showed a disposition to conclude a peace with Rome. However, the republic gave him to understand, that he must not expect to be ranked amongst its friends, until he had delivered up into the consul's hands Jugurtha, the inveterate enemy of the Roman name. The Mauritanian monarch, having entertained a high idea of an alliance with that state, resolved to satisfy it in this particular; and was confirmed in his resolution by one Dabar, a Numidian prince, the son of Massugrada, and descended by his mother's side from Masinissa. Being closely attached to the Romans, and extremely agreeable to Bocchus on account of his noble disposition, he defeated all the intrigues of Aspar, the minister of Jugurtha. Upon Sylla's arrival at the Mauritanian court, the affair there seemed to be entirely settled. However, Bocchus, who was continually projecting new designs, and, like the rest of his countrymen, in the highest degree perfidious, debated within himself whether he should sacrifice Sylla or Jugurtha, who were then both in his power. He was a long time fluctuating in uncertainty, and distracted by a contrariety of sentiments. The sudden changes which displayed themselves in his countenance, his air, and his whole person, evidently showed how strongly his mind was agitated. But at last he returned to his first design, to which the bias of his mind seemed naturally to lead him. He therefore delivered up Jugurtha into the hands of Sylla, to be conducted to Marius, who, by that important event, happily terminated this dangerous war. The kingdom of Numidia was now reduced to a new form. Bocchus, for his important services, had the country of the Massæsyli, contiguous to Mauritania, assigned him, and which, from this time, took the name of New Mauritania. Numidia Propria, or the country of the Massyli, was divided into three parts; one of which was given to Hiempsal, and another to Mandrestal, both descendants of Masinissa; and the third part the Romans annexed to Africa Propria, or the Roman province adjacent to it.

Jugurtha's two sons survived him, but spent their lives in captivity at Venusia. One of them, however, named Oxyntas, was, for a short time, released from his confinement by Aponius, who besieged Acerræ, in the war between the Romans and the Italian allies. That general brought this prince to his army, where he treated him as king, in order to draw off the Numidian forces from the Roman service. Accordingly, those Numidians no sooner heard that the son of their old king was fighting for the allies, than they began to desert by companies; a circumstance which obliged Julius Cæsar the consul to part with all his Numidian cavalry, and send them back into Africa. Some few years after this event, Pompey defeated Cneius Domitius Ahenobarbus, and Hiarbas one of the kings of Numidia, killing seventeen thousand of their men upon the field of battle; and, not satisfied with this victory, that general pursued the fugitives to their camp, which he soon forced, and, having put Domitius to the sword, took Hiarbas prisoner. He then reduced that part of Numidia which belonged to Hiarbas, who seems to have succeeded Mandrestal above mentioned, and gave it to Hiempsal, a neighbouring Numidian prince, descended from Masinissa, who had always opposed the Marian faction.

Suetonius informs us, that a dispute happened between Hiempsal and one Masintha, a noble Numidian, whom, it is probable, he had in some respect injured, at the time when Julius Cæsar first began to make a figure in the world. The same author adds, that Cæsar warmly espoused the cause of Masintha, and even grossly insulted Juba, Hiempsal's son, when he attempted to vindicate his father's conduct on this occasion. He pulled him by the beard, than which a more unpardonable affront could not be offered to an African. In short, he screened Masintha from the insults and violence of his enemies; and from this cause a reason may be assigned for Juba's adhering so closely afterwards to the Pompeian faction.

In consequence of the indignity Cæsar had offered Juba, and the disposition it had occasioned, that prince did Cæsar great damage in the civil wars between him and Pompey. By a stratagem he drew Curio, one of his lieutenants, into a general action, which it was his interest at that time to have avoided. He caused it to be given out over all Africa Propria and Numidia, that he had retired into some remote country at a great distance from the Roman territories. This coming to Curio's ears, who was then besieging Utica, hindered him from taking the necessary precautions against a surprise. Soon afterwards, the Roman general receiving intelligence that a small body of Numidians was approaching his camp, put himself at the head of his forces in order to attack them, and, for fear they should escape, began his march in the night, looking upon himself as certain of victory. Some of their advanced posts he surprised asleep, and cut them to pieces, which still farther animated him. In short, about daybreak he came up with the Numidians, whom he attacked with great bravery, though his men were then fasting, and greatly fatigued by their forced and precipitate march. In the mean time, Juba, who immediately after the propagation of the rumour above mentioned had taken care to march privately, with the main body of the Numidian army, to support the detachment sent before to decoy Curio, advanced to the relief of his men. The Romans had met with a vigorous resistance before he appeared, so that he easily broke them; killed Curio, with a great part of his troops, upon the spot; pursued the rest to their camp, which he plundered; and took many of them prisoners. Most of the fugitives, who endeavoured to make their escape on board the ships in the port of Utica, were either slain by the pursuers, or drowned in the attempt. The remainder fell into the hands of Varus, who would have saved them; but Juba, who arrogated to himself the honour of this victory, ordered most of them to be put to the sword.

This victory infused new life and vigour into the Pompeian faction, who thereupon conferred great honours upon Juba, and gave him the title of king of all Numidia. But Cæsar and his adherents declared him an enemy to the state of Rome, adjudging to Bocchus and Bogud, two African princes entirely in their interest, the sovereignty of his dominions. Juba afterwards, uniting his forces with those of Scipio, reduced Cæsar to great extremities, and would, in all probability, have totally ruined him, had he not been relieved by Publius Sittius. That general, having formed a considerable corps, consisting of Roman exiles, and Mauritanian troops sent him by Bocchus, according to Dio, or, as Cæsar will have it, Bogud, made an irruption into Gætulia and Numidia, whilst Juba was employed in Africa Propria. As he ravaged these countries in a dreadful manner, Juba immediately returned with the best part of his army, in order to preserve them from utter destruction. However, Cæsar knowing that his horse were afraid of the enemy's elephants, did not think proper to attack Scipio in the absence of the Numidian, till his own elephants, and a fresh reinforcement of troops, hourly expected, arrived from Italy. With this accession of strength, he imagined himself able to give a good account, both of the Roman forces with which he was to cope, and of the barbarians. In the mean time Scipio despatched reiterated expresses to Juba to hasten to his assistance, but could not prevail upon him to move out of Numidia, till he had promised him the possession of all the Roman dominions in Africa if they could expel Cæsar from thence. This immediately put him in motion; so that, having sent a large detachment to make head against Sittius, he marched with the rest of his troops to assist Scipio. However, Cæsar at last overthrew Scipio, Juba, and Labienus, near the town of Thapsus, and forced all their camps. As Scipio was the first surprised and defeated, Juba fled into Numidia without waiting for Cæsar's approach; but the body of the Numidians detached against Sittius having been broken and dispersed by that general, none of his subjects there would receive him. Abandoned to despair, he sought death in a single combat with Petreius, and having killed him, caused himself to be despatched by one of his slaves.

After this decisive action, and the reduction of all Africa Propria, Cæsar made himself master of Numidia, which he reduced to a Roman province, appointing Crispus Sallustius to govern it in quality of proconsul, with private instructions to pillage and plunder the inhabitants, and by these means put it out of their power ever to shake off the Roman yoke. However, Bocchus and Bogud still preserved a sort of sovereignty in the country of the Massæsyli and Mauritania; since the former of these princes, having deserted Cæsar, sent an army into Spain to assist the Pompeians; and the latter, with his forces, determined victory in favour of Cæsar at the memorable battle of Munda. Bogud, afterwards siding with Antony against Octavius, sent a body of forces to assist him in Spain; but at this time the Tingitanians having revolted from him, Bocchus, with an army composed of Romans in the interest of Octavius, who passed over from Spain into Africa, and his own subjects, possessed himself of Mauritania Tingitana. Bogud fled to Antony; and Octavius, after the conclusion of the war, honoured the inhabitants of Tingi with all the privileges of Roman citizens. He likewise confirmed Bocchus king of Mauritania Cæsariensis, or the country of the Massæsyli, in the possession of Tingitana, which he had conquered, as a reward for his important services. In this he imitated the example of his great predecessor Julius Cæsar, who divided some of the fruitful plains of Numidia amongst the soldiers of Sittius, who had conquered the greater part of that country, and appointed Sittius himself sovereign of that district. Sittius, as has been intimated above, having taken Cirta, killed Sabura, Juba's general, entirely dispersed his forces, and either cut off or taken prisoners most of the Pompeian fugitives who escaped from the battle of Thapsus, highly deserved to be distinguished in so eminent a manner. After the death of Bocchus, Mauritania and the Massæsylian Numidia were in all respects considered as Roman provinces.

NUMISMATOGRAPHIA, a term applied to the description and knowledge of ancient coins and medals, whether of gold, silver, or brass.

NUN, the son of Elishamah, and father of Joshua, of the tribe of Ephraim. The Greeks gave him the name of *Nane* instead of Nun. This person is only known in sacred history by having been the father of Joshua.

NUN, a woman, in several Christian countries, who devotes herself, in a cloister or nunnery, to a religious life. There were women, in the ancient Christian church, who made public profession of virginity, before the monastic life was known in the world, as appears from the writings of Cyprian and Tertullian. These, for distinction's sake, are sometimes called "ecclesiastical virgins," and were commonly enrolled in the canon or matricula of the church. They differed from the monastic virgins chiefly in this, that they lived privately in their fathers' houses, whereas the others lived in communities; but their profession of virginity was not so strict as to make it criminal for them afterwards to marry, if they thought fit. As to the consecration of virgins, it had some things peculiar in it, and was usually performed publicly in the church by the bishop. The virgin made a public profession of her resolution, and then the bishop put upon her the accustomed habit of sacred virgins. One part of this habit was a veil called the *sacrum velamen*; and another was a kind of mitre or coronet worn upon the head. At present, when a woman is to be made a nun, the habit, veil, and ring of the candidate are carried to the altar; and she herself, accompanied by her nearest relations, is conducted to the bishop, who, after mass and an anthem, pronounces the benediction; upon which she rises up, and the bishop consecrates the new habit, sprinkling it with holy water. When the candidate has put on her religious habit, she presents herself before the bishop, and sings, on her knees, *Ancilla Christi sum;* then she receives the veil, and afterwards the ring, by which she is married to Christ; and, lastly, the crown of virginity. When she is crowned, an anathema is denounced against all who shall attempt to induce her to break her vows.

NUNCIO, or NUNTIO, an ambassador from the pope to some Catholic prince or state, or a person who attends on behalf of the pope at a congress, or an assembly of several ambassadors.

NUNCUPATIVE, in the schools, means something that is only nominal, or has no existence but in name.

NUNCUPATIVE Will or *Testament*, a will made verbally, and not put in writing.

NUNDABAR, a town of Hindustan, in the province of Khandesh, belonging to the Mahrattas, seventy-six miles east from Surat. Long. 74. 15. E. Lat. 21. 17. N.

NUNDAPORAM, a town of Hindustan, in the Northern Circars, and district of Cicacole, eighty-two miles west from Cicacole. Long. 82. 40. E. Lat. 18. 23. N.

NUNDINA, a goddess amongst the ancient heathens, supposed to have had the care of the purification of infants. Because male infants were purified nine days after their birth, her name is derived from *nonus*, or the ninth; although female infants were also purified on the eighth day, which purification was by the Romans called *lustration.*

NUNDINAL, *Nundinalis*, a name which the Romans gave to the first eight letters of the alphabet, which were used in their calendar. This series of letters, A, B, C, D, E, F, G, H, is placed and repeated successively from the first to the last day of the year; and one of these always expressed the market-days or the assemblies called *nundinæ* (quasi novendinæ), because they returned every nine days. The country people, after working eight days successively, repaired to town on the ninth to sell their several commodities, and to inform themselves of all that related to religion and government. Thus the nundinal day being under A on the first, ninth, seventeenth, and twenty-fifth days of January, &c. the letter D will be the nundinal letter of the year following. These nundinals bear a very great resemblance to the dominical letters, which return every eight days, as the nundinals did every nine.

NUNDYDROOG, a celebrated and strong hill fortress of Hindustan, in the province of Mysore. The mountain on which it is built is 1700 feet high, and it is inaccessible on three sides. This fortress, always considered as impregnable, was stormed by the British in 1791, after a siege of three weeks. The neighbouring country is fertile, being studded with hills, in which there is much fertile land. It was long ruled by one of those independent chiefs called poligars in Southern India. He was compelled to pay tribute to Hyder Aly, who ravaged his territories and laid waste the country. Long. 77. 53. E. Lat. 13. 22. N.

NUNEATON, a town of the county of Warwick, in the hundred of Hemlingford, ninety-nine miles from London, and eight from Coventry. It stands on the river Anker, and had formerly a nunnery, to which it owes its name. It partakes of the trade of Coventry, like that place making many ribbons, and, besides, some woollen goods. There is a market on Saturday. The population amounted in 1801 to 4796, in 1811 to 4947, in 1821 to 6610, and in 1831 to 7799.

NUNIA, a village of Irak Arabi, about three quarters of a mile from the Tigris, opposite to Mosul. It is supposed to be the site of the ancient Nineveh. The history of this metropolis is lost in succeeding ages, and it appears to have fallen into decay after the building of Babylon; indeed in the reign of Hadrian it was so completely destroyed, that even the place where it stood was unknown. A city erected afterwards near the spot was called Ninus; and Mr Kinneir is of opinion that it is the ruins of the latter, and not those of old Nineveh, that are still visible. He mentions that he examined these remains in 1810, and that they consisted of a rampart and fosse, forming an oblong square four miles in compass. The wall is on an average twenty feet in height, and is covered with grass, like the Roman intrenchments in England.

NUPTIAL RITES, the ceremonies attending the solemnization of marriage, which are different in different ages and countries. We cannot omit here a custom which was practised by the Romans on these occasions. Immediately after the principal ceremonies were ended, the new married man threw nuts about the room for the boys to scramble for. Various reasons have been assigned for this; but that which most generally prevails, and seems to be the most probable, is, that by this act the bridegroom signified his resolution to abandon trifles, and commence a serious course of life. Hence *nucibus relictis* became in this sense a proverb. The nuts might also be an emblem of fertility. The ancient Greeks had a person to conduct the bride from her own to the bridegroom's house, and hence he was called by the Greeks *Nymphagogus*, which term was afterwards used both by the Romans and the Jews.

NUREMBURG, or NURNBERG, a city of Bavaria, in the circle of the Rezat, and the bailiwick of the same name, of which it is the capital. It is situated on the river Pegnitz, which divides it into two parts. The walls are now kept in a state which renders them indefensible. It is an extensive but thinly peopled city, having much declined from the prosperity it enjoyed in the middle ages, when it was a free imperial city, and the place where the emperors occasionally resided. The city now contains 4500 houses, and 28,200 inhabitants, with eight Lutheran churches, one for the Catholics, and a chapel for the Calvinists. It has also many Jews. It is still a place of considerable manufactures, but they are chiefly on a small scale, furnishing the turnery wares called by its name, cutlery, braziery, looking-glasses, spectacles, needles, mathematical, musical, and surgical instruments, watches, leaf gold and silver, paper, maps, and other articles. It is celebrated as the birthplace of Albert Durer the painter, and the residence of Rudolph the inventor of wire, of Peter Hele the inventor of watches, of Denner the inventor of the clarionet, of Ebner the first cutler, and of Behairn, who first constructed globes. Long. 11. 1. 4. E. Lat. 49. 27. 8. N.

NURPOOR, a town of Hindustan, in the province of Lahore, and capital of a district of the same name. It is situated on the top of a hill, which is ascended by stone steps, and has all the appearance of opulence and industry. It is the residence of a Sikh chief, whose revenue amounts to L.50,000 a year. The district is situated between the thirty-second and thirty-third degrees of north latitude. It belongs to the Sikhs. The city is seventy-five miles east-north-east from the city of Lahore.

NURRAH, a town of Hindustan, in the province of Gundwana, tributary to the Nagpoor rajah, and possessed by native Goand chiefs. It is seventy-eight miles south by east from Ruttunpoor. Long. 82. 45. E. Lat. 21. 2. N.

NURSERY, in *Gardening*, is a piece of land set apart for raising and propagating all sorts of trees and plants to supply the garden and other plantations.

NURSING OF CHILDREN. The following observations and directions were published in the Annual Register (vol. vi. p. 130), as the results of long experience. The child should be laid, the first month, upon a thin mattress, rather longer than itself, which the nurse should keep upon her lap, that the child may always lie straight, and only sit up as the nurse slants the mattress. To set a child quite upright before the end of the first month, would hurt the eyes, by making the white part of the eye appear below the upper eyelid. Afterwards the nurse will begin to set it up and dance it by degrees. The child must be kept as dry as possible.

The clothing should be very light, and not much longer than the child, that the legs may be got at with ease, in order to have them often rubbed in the day with a warm hand or flannel, and in particular the inside of them.

Rubbing a child all over takes off scurf, and causes the blood to circulate. The one breast should be rubbed with the hands one way, and the other the other way, night and morning at least.

The ankle bones and the inside of the knees should be rubbed twice a day; this will strengthen those parts, and make the child stretch its knees and keep them flat, which is the foundation of an erect and graceful person.

A nurse ought to keep a child as little in her arms as possible, lest the legs should be cramped, and the toes turned inwards. Further, she should always keep the child's legs loose. The oftener the posture is changed the better. Tossing a child about, and exercising it in the open air in fine weather, is of the greatest service. In cities, children are not to be kept in hot rooms, but to have as much air as possible. Want of exercise is the cause of large heads, weak and knotted joints, a contracted breast, which occasions coughs and stuffed lungs, an ill-shaped person, and waddling gait, besides a numerous train of other ills.

The child's flesh is to be kept perfectly clean, by constantly washing its limbs, and likewise its neck and ears, beginning with warm water, till by degrees it will not only bear, but like to be washed with cold water.

Rising early in the morning is good for all children, provided they awake of themselves, which they generally do; but they are never to be waked out of their sleep, and as soon as possible to be brought to regular sleeps in the day. When laid in bed or in cradle, their legs are always to be laid straight.

Children, till they are two or three years old, must never be suffered to walk long enough at a time to be weary.

Girls might easily be trained to the proper management of children, if a premium were given in free schools, workhouses, and other places, to those that brought up the finest child to one year old.

If the mother cannot suckle the child, get a wholesome cheerful woman with young milk, who has been used to attend young children. After the first six months, small broths, and innocent foods of any kind, may do as well as living wholly upon milk. A principal thing to be always attended to is, to give young children constant exercise, and to keep them in a proper posture.

With regard to the child's dress in the day, let it be a shirt, a petticoat of fine flannel two or three inches longer than the child's feet, with a dimity top, commonly called a boddice coat, to tie behind; and over that a surcingle made of fine buckram, two inches broad, covered over with satin or fine ticken, with a ribbon fastened to it to tie it on, which answers every purpose of stays, and has none of their inconveniences. Over this put a robe, or a slip and frock, or whatever you like best, provided it is fastened behind, and not much longer than the child's feet, that their motions may be strictly observed. Two caps are to be put on the head, till the child has got most of its teeth. The child's dress for the night may be a shirt, a blanket to tie on, and a thin gown to tie over the blanket.

NUSANCE, or Nuisance, in *Law*, a thing done to the annoyance of another. Nuisances are either public or private. A public nuisance is an offence against the public in general, either by doing what tends to the annoyance of all the king's subjects, or by neglecting to do what the common good requires; in which case, all annoyances and injuries to streets, highways, bridges, and large rivers, as also disorderly ale-houses, gaming-houses, and the like, are held to be common nuisances. A private nuisance is, when only one person or family is annoyed by the doing of any thing; as where a person stops up the light of another's house, or builds in such a manner that the rain falls from his house upon his neighbour's.

NUSSERABAD, a town of Hindustan, in the Mahratta dominions, and province of Berar, forty-two miles south-west from Burhampoor. Long. 75. 51. E. Lat. 20. 56. N.

NUSSERITABAD, or Sackur, a town of Hindustan, in the province of Bejapore, belonging to the nizam.

NUSSERPOOR, a town of Hindustan, in the province of Sinde, and the capital of a district of the same name, situated near the banks of the Indus. Long. 69. 10. E. Lat. 25. 28. N. The district is situated principally between the twenty-sixth and twenty-seventh degrees of north latitude, and is intersected by the river Indus.

NUT, among botanists, denotes a *pericarpium* of an extraordinary hardness, enclosing a kernel or seed.

NUTATION, in *Astronomy*, a kind of tremulous motion of the axis of the earth, by which, in each annual revolution, it is twice inclined to the ecliptic, and as often returns to its former position.

NUTHUIRS, a village of Persia, in the province of Irak, situated on a small plain surrounded with mountains, on the road from Ispahan to Sultania, and sixty-three miles north from Ispahan.

NUTMEG, the fruit of a tree, and a well-known spice. See Myristica.

NUTRITION, in the animal economy, is the repairing the continual loss which the different parts of the body undergo. The motion of the parts of the body, the friction of these parts against each other, and especially the action of the air, would destroy the body entirely, if the loss was not repaired by a proper diet containing nutritive juices, which being digested in the stomach, and afterwards converted into chyle, mix with the blood, and are distributed throughout the whole body for its nutrition.

Buffon, in order to account for nutrition, supposes the body of an animal or vegetable to be a kind of mould, in which the matter necessary to its nutrition is modelled and assimilated to the whole. But of what nature is this matter which an animal or a vegetable assimilates to its own substance? What power is it that communicates to this matter the activity and motion necessary to penetrate this mould? and, if such a force exist, would it not be by a similar force that the internal mould itself might be reproduced?

As to the first question, he supposes that there exists in nature an infinite number of living organical parts, and that all organized bodies consist of such organical parts; that their production costs nature nothing, since their existence is constant and invariable; so that the matter which the animal or vegetable assimilates to its substance is an organical matter of the same nature with that of the animal or vegetable, which consequently may augment its volume without changing its form or altering the quality of the substance in the mould.

As to the second, there exist in nature certain powers, as that of gravity, which have no affinity with the external qualities of the body, but act upon the most intimate parts, and penetrate them throughout, and which can never fall under the observation of our senses.

And as to the third, he conceives that the internal mould itself is reproduced, not only by a similar power, but by the very same power which causes the unfolding and reproduction thereof. For it is sufficient, he thinks, that, in an organized body which unfolds itself, there should be some part similar to the whole, in order that this part may one day become itself an organized body, altogether like that of which it is actually a part.

NUX VOMICA, a flat, compressed, round fruit, about the breadth of a shilling, brought from the East Indies. It is found to be a certain poison for dogs, cats, and other animals, and it is not to be doubted that it would also prove fatal to man. Its surface is not much corrugated, and its texture is firm like horn, and of a pale grayish-brown colour. It is said to be used as a specific against the bite of a species of water-snake. It is considerably bitter and deleterious; but has been used in doses of from five to ten grains twice a day or so, in intermittents, particularly obstinate quartans, and in contagious dysentery. The *strychnus Ignatii* is a tree of the same kind producing gourd-like fruit, the seeds of which are improperly called St Ignatius's beans. These, as also the woods or roots of some such trees, called *lignum colubrinum*, or snakewood, are very narcotic bitters, like the *nux vomica.*

NUYTS, PETER, a native of Holland, and a leading character in that extraordinary transaction which happened between the Japanese and the Dutch about the year 1628. In 1627 Nuyts arrived in Batavia from Holland, and was in the same year appointed ambassador to the emperor of Japan, by the governor and council of Batavia. He repaired to that empire in 1628; and being a man of a haughty disposition, and extremely vain, he believed it practicable to pass upon the natives for an ambassador from the king of Holland. Upon his assuming this title and rank, he was much more honourably received, caressed, and respected than former ministers had been. But he was soon detected, reprimanded, and reproached in the severest manner, sent back to the port, and ordered to return to Batavia with all the circumstances of disgrace imaginable; notwithstanding which, his interest was so great, that, instead of being punished as he deserved, he was immediately afterwards promoted to the government of the island of Formosa, of which he took possession in the following year. He entered upon the administration of affairs in that island with the same disposition that he had shown whilst ambassador, and with the most implacable resentment against the Japanese; neither was it long before an opportunity offered, as he thought, of revenging himself on them to the full. Two large Japanese ships, with upwards of five hundred men on board, came into the port, upon which he took it into his head to disarm and unrig them, in the same manner as the Dutch vessels are treated at Japan. The Japanese did all they could to defend themselves from this ill usage; but at last, for want of water, they were forced to submit. Governor Nuyts went still farther. When they had finished their affairs at Formosa, and were desirous of proceeding, according to their instructions, to China, he put them off with fair words and fine promises, till the monsoon was over. They then began to be very impatient, and desired to have their cannon and sails restored, that they might return home; but the governor had recourse to new artifices, and, by a series of false promises, endeavoured to prevent them from making use of the season most proper for that voyage. The Japanese, however, soon perceived his design, and at length, by a bold attempt, accomplished what, by fair means and humble entreaty, they could not obtain; for, by a daring and well concerted effort, they took him prisoner, and compelled him and one of the council to sign a treaty for securing their liberty, free departure, and indemnity, which was afterwards ratified by the whole council. Nuyts was first confined in Batavia, and afterwards delivered up to the Japanese, notwithstanding the most earnest entreaties on his part to be tried, and even to suffer any kind of death, where he was, rather than to be sent to Japan. Thither, however, he was sent in 1634, when he was submitted to the mercy or discretion of the emperor; and the consequence was, that, though imprisoned, he was well used, and could go anywhere, provided his guards were with him, which was more than he could possibly have expected. He now looked for nothing but the continuance of his confinement for life. On a particular occasion, however, namely, the funeral of the emperor's father, he was, at the request of the Dutch, set free, and returned again to Batavia, to the surprise of the people of that settlement, who adopted ever afterwards a very different conduct with respect to the Japanese.

NUYTS' REEFS, several large reefs of rocks which lie off the south coast of New Holland, at Cape Nuyts. These reefs are about eight miles distant from the coast, and are eight miles in length. In some places the rocks rise above the water, and in others they are wholly concealed. Long. of Cape Nuyts, 132. 18. E. Lat. 32. 2. S.

NUZZER, or MUZZERANAH, a present or offering from an inferior to a superior. In Hindustan no man ever approaches his superior for the first time on business without an offering of at least a gold or silver rupee in his right hand; and if this be not taken, it is a mark of disfavour. Nuzzeranah is also used to signify the sum paid to the government as an acknowledgment for a grant of lands or any public office.

NYCHTHEMERON, amongst the ancients, signified the whole natural day, or day and night, consisting of twenty-four hours, or twenty-four equal parts. This way of considering the day was particularly adopted by the Jews, and seems to have owed its origin to the expression of Moses in the first chapter of Genesis, "The evening and the morning were the first day." Before the Jews had introduced the Greek language into their discourse, they were accustomed to indicate this space of time by the simple expression of a night and a day.

It is proper here to observe, that in all the eastern countries any part of a day of twenty-four hours was reckoned for a whole day; and that a thing which was done on the third or seventh day from that last mentioned, was said to be done after three or seven days. The Hebrews, having no word which exactly answered to the Greek Νυχθημερον, signifying a natural day of twenty-four hours, used *night and day*, or *day and night*, instead of it; so that to say a thing happened after three days and three nights, was, with them, the same as to say that it happened after three days, or on the third day. This being remembered, will explain what is meant by "the Son of Man's being three days and three nights in the heart of the earth."

NYCTASTRATEGI, amongst the ancients, were officers appointed to prevent fires in the night, or to give alarm and call assistance when a fire broke out. At Rome they had the command of the watch, and were called *nocturni triumviri*, from their office and number.

NYIREGYHAZA, a town of the circle of Szaboles, in the province of Farther Theiss, in Hungary. It contains a Catholic, a Lutheran, a Calvinist, and an Unitarian church, a public grammar-school, 1100 houses, and 8066 inhabitants, who are employed in cultivating the vine, and in several trades. Long. 22. 38. 10. E. Lat. 47. 56. 45. N.

NYKOPING, a province of the west of Sweden, which extends in north latitude from 58. 36. to 59. 30., and in east longitude from 15. 28. to 17. 33., and contains 2977 square miles. It comprises seven cities or towns, and 3327 detached settlements, with 98,500 inhabitants. It is a district of mountains and lakes, intermingled with extensive woods, but barely produces corn sufficient for its scanty population. The chief occupation consists in copper and iron mines, and in the fishery. The capital is a city of the same name, situated on a bay in the Baltic Sea.

It is a well-built town, and has a market-place, surrounded with houses of stone, but most of the others are of wood. It contains two churches, and 520 dwellings, with 2490 inhabitants, who make cutlery and bar iron, and export large quantities of deals and other wood. Long. 16. 57. 10. E. Lat. 58. 45. 30. N.

NYLACKY, one of the Banda Islands, in the Eastern Seas. Long. 130. 33. E. Lat. 4. 11. S.

NYMPH, in *Mythology*, an appellation given to certain inferior goddesses, inhabiting the mountains, woods, and waters, and said to have been the daughters of Oceanus and Tethys. All the universe was represented as full of these nymphs, who were distinguished into several ranks or classes. The general division of them was into celestial and terrestrial. The former were called *Uraniæ*, and were supposed to be intelligences which governed the heavenly bodies or spheres. The terrestrial nymphs, called *Epigeiæ*, were believed to preside over the several parts of the inferior world, and were divided into those of the water and those of the earth. The nymphs of the water were the *Oceanitides*, or nymphs of the ocean; the *Nereids*, or the nymphs of the sea; the *Naiads* and *Ephydriades*, or the nymphs of the fountains; and the *Limniades*, or the nymphs of the lakes. The nymphs of the earth were the *Oreades*, or nymphs of the mountains; the *Napææ*, or nymphs of the meadows; and the *Dryads* and *Hamadryads*, who were nymphs of the forests and groves. Besides these, we meet with nymphs who took their names from particular countries, rivers, and places.

"The nymphs," says Dr Chandler, "were supposed to enjoy longevity, but not to be immortal. They were believed to delight in springs and fountains. They are described as sleepless, and as dreaded by the country people. They were susceptible of passion. The Argonauts, it is related, landing on the shore of the Propontis to dine, in their way to Colchis, sent Hylas, a boy, for water, who discovered a lonely fountain, in which the nymphs Eunica, Malis, and Nycheia, were preparing to dance; and these seeing him were enamoured, and, seizing him by the hand as he was filling his vase, pulled him in. The deities, their copartners in the cave, are such as presided with them over rural and pastoral affairs.

"The old Athenians were ever ready to cry out, a gód, or a goddess. The tyrant Pisistratus entered the city in a chariot with a tall woman dressed in armour to resemble Minerva, and regained the Acropolis, which he had been forced to abandon, by this stratagem; the people worshipping, and believing her to be the deity whom she represented. The nymphs, it was the popular persuasion, occasionally appeared; and nympholepsy is characterised as a frenzy which arose from having beheld them. Superstition disposed the mind to adopt delusion for reality, and gave to a fancied vision the efficacy of full conviction. The foundation was perhaps no more than an indirect, partial, or obscure view of some harmless girl, who had approached the fountain on a like errand with Hylas, or was retiring after she had filled her earthen pitcher.

"Amongst the sacred caves on record, one on Mount Ida in Crete was the property of Jupiter, and one by Lebadea in Bœotia, of Trophonius. Both these were oracular, and the latter bore some resemblance to that which we have described. It was formed by art, and the mouth surrounded with a wall. The descent to the landing place was by a light and narrow ladder, occasionally applied and removed. It was situated on a mountain above a grove; and the story goes, that a swarm of bees conducted the person by whom it was first discovered. But the common owners of caves were the nymphs, and these were sometimes local. On Cithæron, in Bœotia, many of the inhabitants were possessed by nymphs called *Sphragitides*, whose

cave, once also oracular, was upon a summit of the mountain. Their dwellings had generally a well or spring of water, the former being often a collection of moisture condensed or exuding from the roof and sides; and this, in many instances, being pregnant with stony particles, concreted and marked its passage by incrustation, the groundwork, in all ages and countries, of idle tales framed or adopted by superstitious and credulous people.

"A cave in Paphlagonia was sacred to the nymphs who inhabited the mountains about Heraclea. It was long and wide, and pervaded by cold water clear as crystal. There also were seen bowls of stone, and nymphs and their webs and distaffs, and curious work, exciting admiration. The poet who has described this grotto does not deserve to be regarded as servilely copying Homer; he may justly lay claim to rank as an original topographer.

"The piety of Archidamus furnished a retreat for the nymphs, where they might find shelter and provision, if distressed; whether the sun parched up their trees, or Jupiter, enthroned in clouds upon the mountain top, scared them with his red lightning and terrible thunder, pouring down a deluge of rain, or brightening the summits with his snow."

NYMPH, amongst naturalists, that state of winged insects between their living in the form of a worm and their appearing in the winged or more perfect state. See ENTOMOLOGY.

NYMPHÆA, amongst the ancients, certain structures, although it is doubtful of what kind they were. Some take them to have been grottoes, deriving their name from the statues of the nymphs with which they were adorned; but that they were considerable works, appears from their having been executed by the emperors, or by the city prefects. In an inscription, the term is written *nymfium*. None of all these *nymphæa* has remained till our time. A number of years ago, indeed, a square building of marble was discovered between Naples and Vesuvius, with only one entrance, and some steps leading down to it. On the right hand as you enter, towards the head, there is a fountain of the purest water, along which, by way of guardian, is placed a naked Arethusa of the whitest marble. The bottom or ground is of variegated marble, and encompassed with a canal fed by the water from the fountain. The walls are set round with shells and pebbles of various colours, by which are expressed the twelve months of the year, and the four political virtues, as also the rape of Proserpine; Pan playing on his reed, and soothing his flock; and the representations of nymphs swimming, sailing, and wantoning on fishes. It seems pretty evident that the *nymphæa* were public baths; for at the same time that they were furnished with pleasing grottoes, they were also supplied with cooling streams, by which they were rendered exceedingly delightful, and drew great numbers of people to frequent them. Silence seems to have been a particular requisite in these retreats, as appears by this inscription, *Nymphis loci, bibe, lava, tace.* The building between Naples and Vesuvius, mentioned above, was certainly one of these *nymphæa*.

NYSA, or NYSSA, in *Ancient Geography*, a town of Ethiopia, to the south of Egypt. Some place it in Arabia. This city, with another of the same name in India, was sacred to the god Bacchus, who was supposed to have been educated there by the nymphs of the place, and who received the name of *Dionysus*, which seems to be compounded of Διος and Νυσα, the name of his father, and that of the place of his education. The god is believed to have made this place the seat of his empire, and the capital of the conquered nations of the East. According to some geographers, there were no less than ten places of this name.

O.

O || Oak.

O, THE fourteenth letter and fourth vowel of our alphabet, being pronounced as in the words *nose, rose, hose.* The sound of this letter is often so soft as to require it double, and that chiefly in the middle of words, as *goose, reproof, woof;* and in some words this double *oo* is pronounced like *u* short, as in *blood, flood.* As a numeral, O was sometimes used for 11 amongst the ancients, and with a dash over it, thus, Ō, it stood for 11,000. In the notes of the ancients, O. CON. is read *opus conductum;* O. C. Q. *opera consilioque;* O. D. M. *operæ donum munus;* and O. LO. *opus locatum.* The Greeks had two O's, namely, the omikron, ο, and the omega, ω; the one being pronounced on the tip of the lips with a sharper sound, and the other in the middle of the mouth, with a fuller sound, equal to *oo* in our language. The long and short pronunciations of our O are equivalent to the two Greek ones. O is usually denoted as long by a servile *a* subjoined, as *moan;* or by *e* at the end of the syllable, as *bone;* but when these vowels are not used it is generally short. Amongst the Irish, the letter O, at the beginning of the name of a family, is a character of dignity annexed to great houses. Thus, in the history of Ireland, we frequently meet with the *O'Neals, O'Carrols,* and *O'Connells,* considerable personages in that island. Indeed Campden observes, that it is the custom of the lords of Ireland to prefix an O to their names, to distinguish them from the commonalty. The ancients used O as a mark of triple time, from a notion that the ternary, or number 3, was the most perfect of numbers, and therefore properly expressed by a circle, which is the most perfect of figures. It is not, strictly speaking, the letter O, but the figure of a circle O, or double CO, by which the early moderns used to express in music what they called *tempo perfecto,* or triple time; and hence the Italians call it *circolo.* The seven antiphones, or alternate hymns of seven verses, sung by the choir in the time of Advent, were formerly called O, from their beginning with such an exclamation.

O, or OH, is an adverb of calling, or interjection of sorrow or wishing.

OAK. The oak has long been known by the title of "monarch of the woods," and, we may add, justly.

The ancient Druids had a profound veneration for oak trees. Pliny says that "the Druids, as the Gauls call their magicians or wise men, held nothing so sacred as the misletoe, and the tree on which it grows, provided it be an oak. They make choice of oak groves in preference to all others, and perform no rites without oak leaves; so that they seem to have the name of Druids from thence, if we derive their name from the Greek."

This useful tree grows to such surprising magnitude, that were there not many well-authenticated instances in our own country, it would certainly appear difficult to believe that it could attain such size. In the eighteenth volume of the Gentleman's Magazine we have the dimensions of a leaf twelve inches in length and seven in breadth; and all the leaves of the same tree were equally large. On the estate of Woodhall, purchased in 1775 by Sir Thomas Rumbold, an oak was felled which sold for L.43, and measured twenty-four feet in circumference. We are also told of one in Millwood Forest, near Chaddesley, which was in full verdure in winter, getting its leaves again, after the autumnal ones fell off. In Evelyn's *Sylva,* we have an account of a very remarkable oak at Greendale, which Gough, in his edition of Campden, thus minutely describes: "The Greendale oak, with a road cut through it, still bears one green branch. Such branches as have been cut or broken off are guarded from wet by lead. The diameter of this tree at the top, whence the branches issue, is fourteen feet two inches; at the surface of the ground eleven feet and a half, circumference there thirty-five feet; height of the trunk fifty-three; height of the arch ten, width six. Mr Evelyn mentions several more oaks of extraordinary size in Worksop Park."

M. Hamel du Monçeau, a member of the Royal Academy of Sciences at Paris, gave an account, in the year 1749, of an oak which he had kept in water eight years, and which yielded fine leaves every spring. The tree, he says, had four or five branches; the largest nineteen or twenty lines round, and more than eighteen inches in length. It throve more in the first two years than it would have done in the best earth; but it afterwards lost its vigour, and rather decayed, which he attributed more to a defect in the roots than to a want of aliment.

Buffon made some experiments upon oak trees, the result of which is recorded in the Gentleman's Magazine, 1754. He had compared barked with unbarked trees, and concluded, from a variety of trials, that timber barked and dried standing, is always heavier and considerably stronger than timber kept in its bark.

The use of oak bark in tanning, and in hot-beds, is generally known. For the latter of these purposes, however, oak leaves are now found to answer equally well, or rather better. In the notes to Dr Hunter's edition of Evelyn's Treatise on Forest Trees, we find certain directions for their use, by Mr Speechly. The leaves are to be raked up as soon as possible after they fall from the trees. When raked into heaps, they should immediately be carried into some place near the hot-houses, where they may lie to couch. It is the custom of some to fence them round with charcoal hurdles, or any thing to keep them from being blown about the garden in windy weather. They are then trodden well, and watered in case they happen to have been brought in dry. The heap is made six or seven feet thick, and covered over with old mats, or any thing else, to prevent the upper leaves from being blown away. In a few days the heap will attain a strong heat. For the first year or two in which he used these leaves, Mr Speechly did not continue them in the heap longer than ten days or a fortnight; but by this method of management they settle so much when brought to the hot-house, that a supply was very soon required; and he afterwards found, that it was proper to let them remain five or six weeks in the heaps before they were brought to the hot-house. In getting them into the pine pots, if they appear dry, they are to be watered, and again trodden down exceedingly well, in layers, till the pits are quite full. The whole is then covered with tan bark, to the thickness of two inches, and well trodden down, till the surface becomes smooth and even. The pine pots are then to be placed in the manner in which they are to stand, beginning with the middle row first, and filling up the spaces between the pots with tan. In this manner we are to proceed to the next row, till the whole be finished; and the operation is performed in the same manner as when tan only is used. The leaves require no further trouble through the whole season, as they will retain a constant and regular heat during twelve months without stirring or turning; and Mr Speechly informs us, that if he might judge from their appearances when taken out, being always entire and perfect, it was probable they would continue their heat through a second year; but, as an annual supply of leaves is easily obtained, the experiment is hardly worth making. After this, the pines will have no occasion to be moved except at stated times of their management, as at the shifting them in their pots, when at each time a little fresh tan should be added to make up the deficiency arising from the settling of the beds; but this will be inconsiderable, as the leaves do not settle much after their long couching. During the first two years of our author's practice he did not use any tan, but plunged the pine pots into the leaves, and merely covered the surface of the beds, when finished, with a little saw-dust, to give it a neatness. This method, however, was attended with one inconvenience; for, by the caking of the leaves, they shrunk from the sides of the pots, by which they became exposed to the air, and at the same time the heat of the beds was permitted to escape. See Planting.

Oak-Leaf Galls. These are of several kinds. The remarkable species called the *mushroom gall* is never found on any other vegetable substance than these leaves; and, besides this, there is a great number of other kinds.

The double gall of these leaves is very singular, because the generality of productions of this kind affect only one side of a leaf or branch, and grow all one way; whereas this kind of gall extends itself both ways, and is seen upon each side of the leaf, in the form of two protuberances, the one opposite to the other. These are of differently irregular shapes; but their natural figure seems that of two cones, with broad bases and very obtuse points, though they are sometimes round, or very nearly so.

These make their first appearance on the leaf in April, and remain on it till June, or even longer. They are at first green, but afterwards yellowish, and are softer to the touch than many other of the productions of this kind. They are usually about the size of a large pea, but sometimes they grow to the size of a nut. When opened, they are found to be of that kind which is inhabited each by one insect only, and contains but one cavity. The cavity in this, however, is larger than in any other gall of the size, or even in many others of three times its size; the sides of it being very little thicker than the substance of the leaf.

OAKA, a town of Hindustan, in the province of Gujerat, and capital of a district of the same name. It was long the residence of a gang of pirates, who preyed upon the trade and shipping that frequented those seas. They at length received a severe chastisement from the East India Company's marine, and afterwards agreed to respect the British flag. These rude people were accustomed to rely for protection in their piratical adventures upon an idol at the temple of Dwaraca, to which they vowed a large share of the plunder provided they were successful; and they were accordingly instigated to piracy by the priests of the temple, who were large sharers in the booty acquired. The district of Oaka or Oakamundal is situated on the Gulf of Cutch, and separated from the mainland by the swamp called the Runn. The few quiet inhabitants who reside in it breed a number of camels, which browse on the shrubs growing around the swamp; but the greater number of the people are pirates. Long. of the town 69. 36. E. Lat. 22. . N.

OAKHAMPTON, a borough and market town in the county of Devon, and hundred of Lifton, 195 miles from London, and twenty-one from Exeter. There is very little trade in this place, the manufacture of serges having of late years disappeared. The corporation consisted of a mayor, burgesses, a recorder, and eight aldermen. It returned two members to parliament till 1832, but it is now disfranchised. The population amounted in 1801 to 1430, in 1811 to 1440, in 1821 to 1907, and in 1831 to 2055.

OAKINGHAM, or Wokingham, a market-town of the hundred of Sonning, in the county of Berks, but with the singularity, that a part of the town, including the church, is in the hundred of Amesbury, and the county of Wilts. It is thirty-two miles from London, and seven from Reading, and is situated on the border, within the boundary of the royal forest of Windsor. It consists of four streets meeting in the market-place, where is the town-hall. The church is an extensive structure, supported by handsome pillars, and adorned by many monuments. It has a good free school, and some charities, particularly one endowed by Archbishop Laud for female servants. A well-furnished market is held every Tuesday. The number of inhabitants, including the parts of both counties, amounted in 1801 to 2027, in 1811 to 2085, in 1821 to 2490, and in 1831 to 2692.

OANNES, a being in Chaldaic mythology, represented as half a man and half a fish. According to Berosus and other fabulous writers, this monster was the civilizer of the Chaldæans, to whom he is said to have taught a system of jurisprudence so perfect as to be incapable of further improvement. In discharging the duties of his office, he is said to have spent the day on dry land, but to have retired every night into the ocean or the river.

OAR, a long piece of timber, flat at one end and round or square at the other, and which being applied to the side of a floating vessel, serves to propel, or cause it to advance upon the water.

That part of the oar which is out of the vessel, and which enters into the water, is called the *blade* or *wash-plat*; and that which is within board is termed the *loom*, the extremity of which, being small enough to be grasped by the rowers or persons managing the oars, is called the *handle*.

OARISTUS, or Oaristys, a term in Greek poetry, signifying a dialogue between a husband and his wife; as that in the sixth book of the Iliad, between Hector and Andromache. Scaliger observes, that the oaristus is not properly any particular little poem, or entire piece of poetry, but always a part of a great one; and that the passage in Homer here referred to is the only proper oaristus extant in ancient poetry.

OASIS, the name of a fertile spot in the midst of a sandy desert. Many of these spots, or *oases*, in the African deserts, are remarkable for their fertility.

OATH, an affirmation or promise, accompanied with an invocation of God to witness what we say, and with an imprecation of his vengeance, or a renunciation of his grace, if what we affirm be false, or what we promise be not performed. The word is a corruption of the Saxon *eoth*; and in England it is often called a *corporal oath*, because, in the days of Catholicism, the person was sworn upon the host or *corpus Christi*.

The laws of all civilized states have required the security of an oath for evidence given in a court of justice, and on other occasions of high importance; but the Quakers and some other sects refuse to swear on any occasion, even at the requisition of a magistrate, and in a court of justice. The text of Scripture upon which the Quakers principally rest their argument for the unlawfulness of all swearing, is our Saviour's prohibition, "I say unto you, swear not at all." But it is only in ordinary conversation, and by no means in courts of justice, that Christ prohibits his followers from swearing at all. There is no evidence whatever, that swearing by heaven, by the earth, by Jerusalem, or by their own heads, was the form of a judicial oath in use amongst the Jews. On the contrary, we are told by Maimonides, that "if any man swear by heaven or

Oath. by earth, yet this is not an oath;" which, surely, he could not have said had such been the forms of judicial swearing. Indeed the Jews could not have admitted such forms into their courts without expressly violating the law of Moses, who commands them to "Fear Jehovah their God, to serve him, and to swear by his name." But the Jews, as every one knows, had such a reverence for the name of Jehovah, that they would not pronounce it on slight occasions, and therefore could not swear by that name in common conversation. Hence, to gratify their propensity to common swearing, they invented such oaths as, by heaven, by earth, by Jerusalem, by the life of thy head, and such like, and by this contrivance they thought to avoid the guilt of profaning the name of Jehovah. These, however, being appeals to insensible objects, either had no meaning, or were in fact, as our Saviour justly argues, oaths by that God whose creatures they were; so that the Jew who swore them was still guilty of profaneness towards the very Jehovah whose name his superstition would not permit him to pronounce. But what puts it beyond all doubt that the use of judicial oaths is not wholly prohibited in the gospel, is the conduct of our Saviour himself, as well as that of his apostle St Paul. When Jesus was simply asked by the high priests, what it was which certain false witnesses testified against him, we are told by the evangelists, that "he held his peace;" but being adjured by the living God to declare whether he was the Christ, the Son of God, or not, he immediately answered the high priest, without objecting to the oath (for such it was) upon which he was examined. St Paul, in his Epistle to the Romans, says, "*God is my witness*, that, without ceasing, I make mention of you in my prayers;" and to the Corinthians, still more strongly, "*I call God for a record upon my soul*, that, to spare you, I came not as yet to Corinth." Both these expressions are of the nature of oaths; and the author of the Epistle to the Hebrews speaks of the custom of swearing judicially without any mark of censure or disapprobation: "Men verily swear by the greater; and an oath, for confirmation, is to them an end of all strife."

But although a nation has an undoubted right to require the security of an oath upon occasions of real importance, it is something worse than bad policy to multiply oaths, and to hold out to the people temptations to perjure themselves. The security which an oath affords depends entirely upon the reverence which attaches to it in the mind of him by whom it is given; but that reverence is much weakened by the frequency of oaths, and by the careless manner in which they are too often administered. Paley observes, with truth, that "the levity and frequency with which oaths are administered, has brought about a general inadvertency to the obligation of them, which, both in a religious and political view, is much to be lamented; and it merits," continues he, "public consideration, whether the requiring of oaths on so many frivolous occasions, especially in the customs, and in the qualification for petty offices, has any other effect than to make them cheap in the minds of the people. A pound of tea cannot travel regularly from the ship to the consumer without costing half a dozen oaths at least; and the same security for the due discharge of his office, namely, that of an oath, is required from a churchwarden and an archbishop, from a petty constable and the chief justice of England. Let the law continue its own sanctions if they be thought requisite, but let it spare the solemnity of an oath; and where it is necessary, from the want of something better to depend upon, to accept a man's own word or own account, let it annex to prevarication penalties proportioned to the public consequence of the offence."

Besides the frequency of oaths, we have mentioned the irreverent manner in which they are too often administered as one of the causes which make them cheap in the estimation of the people. In this view, the form of the oath, and the ceremonies with which it is required to be taken, are of considerable importance. "The forms of oaths in Christian countries," says Paley, "are very different; but in none, I believe, worse contrived, either to convey the meaning or to impress the obligation of an oath, than in England."

Oaths are either assertory or promissory. Assertory oaths are required both to confirm our veracity in evidence, and to give security to the public, that we believe certain propositions conceived to be of public importance. An oath in evidence binds the juror to declare what he knows to be true, and nothing but what he knows to be true. An oath required to assure the public of our belief in the truth of any proposition cannot, without the guilt of perjury, be taken by any man, who, at the time of swearing, has the slightest doubt in his mind whether the proposition be really true. Such an oath, however, though it unquestionably requires the sincerity of the juror's belief at the time when it is given, cannot oblige him to continue in that belief as long as he may live; for belief is not in any man's power, being the necessary consequence of evidence, which compels the assent of the mind, according as it appears to preponderate on the one side or on the other. No man, therefore, can be justly accused of perjury for holding opinions contrary to those which he may formerly have sworn to believe; because his belief at the time of emitting his oath may have been the necessary result of the evidence which then appeared before him, and his change of opinion may have resulted with the same necessity from superior evidence which had been since then thrown into the opposite scale, and made it preponderate. On this account we cannot help thinking that all assertory oaths, excepting such as are necessary to confirm testimony respecting facts, ought either to be abolished, or expressed with great caution. Of truths intuitively certain, or capable of rigid demonstration, no man of common sense can entertain a doubt; and therefore the public never requires from individuals the solemnity of an oath as an assurance of their believing such truths. But with respect to the truth of propositions which admit of nothing superior to moral evidence upon either side, a man of the most steady virtue may think differently at different periods of his life; and in such cases, the effect of an oath, if it have any effect, can only be either to shut the man's eyes against the light, or to make his integrity be causelessly questioned by those who may observe his change of belief.

Promissory oaths cannot, without the guilt of perjury, be given by him who, at the time of swearing, knows that it will not be in his power to fulfil the promise, or who does not seriously intend to fulfil it. A promissory oath cannot, without great guilt, be given by any man, who at the time of swearing believes the object of the promise to be in itself unlawful; for if he seriously mean to fulfil his oath, he calls upon Almighty God to witness his intention to commit a crime. Promissory oaths give to the public greater security than a simple promise; because the juror having the thoughts of God and of religion more upon his mind at the one time than at the other, offends with a higher hand, and in more open contempt of the divine power, knowledge, and justice, when he violates an oath, than when he breaks a simple promise. Yet it is certain that promissory oaths, though more solemn and sacred, cannot be binding when the promise without an oath would not be so, though in an inferior degree.

OAXACA, one of the states of the republican confederacy of Mexico. See the article MEXICO.

OAXACA, the capital city of a state of the same name in the republic of Mexico. It is built on the site of the ancient Huaxyacac, and bore the name of Antequera at the time of the conquest. Its situation is in a delightful valley, forty miles in length by twenty in breadth, and it lies

230 miles south of the city of Mexico. Oaxaca is built in the form of an oblong square, being nearly two miles by one and a quarter in extent, including the suburbs, which are principally occupied by gardens. It is one of the neatest, cleanest, and most regularly built towns in Mexico. The streets are wide and well paved; and there are a number of squares, the beauty of which is enhanced by the presence in all of them of handsome public fountains. The edifices are constructed of a green stone, which, preserving its colour to perpetuity, gives the city a singular appearance of freshness. The convent of San Francisco, situated in the great square, was erected above two hundred years ago, yet it still retains the appearance of a new building. There are a number of public edifices in Oaxaca, including several churches, which are solidly built, and richly decorated. The climate is considered as unsurpassed for salubrity and equability by any in the republic, the thermometer rarely falling below 63°, nor ranging higher than 78°. The markets are supplied with fruits both of the temperate and torrid zones, raised in the vicinity; and it is no uncommon thing to see trees loaded with oranges on one side of the road, and fields of wheat extending on the other. Oaxaca was formerly more populous than it is at present, having suffered a good deal during the revolutionary struggle; but the inhabitants still amount to about 20,000.

OBA, a town of Persia, in the province of Azerbijan, at the head of a small gulf on the western coast of the Caspian, and on one of the mouths of the Kur, about 150 miles north-east of Tabreez.

OBADIAH, or the *Prophecy* of OBADIAH, a canonical book of the Old Testament, contained in a single chapter. It is partly an invective against the cruelty of the Edomites, who mocked and derided the children of Israel as they passed into captivity, and, with their confederates, invaded and oppressed these strangers, dividing the spoil amongst themselves; and partly a prediction of the deliverance of Israel, and of the victory and triumph which the church would gain over her enemies.

OBAN, a neat and small modern town in the parish of Kilbride, lordship of Lorn, and county of Argyle, ninety-two miles from Glasgow, and 136 from Edinburgh. The situation of the town is well chosen, both as regards the picturesque scenery amidst which it is placed, the convenient station which its bay affords for national purposes, as the dépôt for the trade of the Hebrides and the western coast of the Highlands, and as being admirably designed for a fishing station. The bay of Oban, at the head of which the town lies, is semicircular, being formed by the island of Kerrera in front, and, backed by the huge ranges of the Argyleshire mountains; it is well sheltered from the western winds by the island of Kerrera, varies from twelve to twenty-four fathoms in depth, and is capable of containing from three to five hundred sail of merchantmen. The steamers from Glasgow and Liverpool, which visit the western coast and Inverness by the Crinan and Caledonian Canals, generally stop at Oban; and, from the salubrity of the air, and moderate rate of the markets, it is much resorted to as bathing quarters during the summer months, and many respectable families have now made it their permanent place of residence. The territory of the burgh consists of the lands of Oban and Glenshellich, with the ferry-house, miller's croft, and loch, and the lands of Glencrutten. This territory, however, extends considerably beyond the parliamentary bounds assigned to the town by the burgh reform act. The town is divided by a small river into two divisions, called the eastern and western. In the eastern a handsome church was erected in the year 1821 as a chapel of ease to the parish church, which is at a distance of four miles from the town. It was constituted a port of customs in the year 1763; and the custom-house is pleasantly placed upon a rising situation, so as to command a view of the bay. The superiors and proprietors of the burgh are the Duke of Argyll and Mr Campbell of Combie. These proprietors and their predecessors, as soon as they observed that some trade had begun to be carried on, granted building leases of portions of their lands upon the most liberal terms, and under this system it rapidly increased. Oban was first erected into a burgh of barony in 1811 by the Duke of Argyll, with the consent of Mr Campbell. This charter was, however, laid aside, on grounds arising out of the titles of the Argyll estates; and Mr Campbell having in the mean time acquired the superiority of his lands, a new charter was granted in the year 1820. There are no public buildings belonging to the burgh, nor public institutions of any kind; neither is it possessed of any property or annual revenue, nor encumbered with any amount of debt. The magistrates and council have no power to tax or assess the inhabitants, and no taxes have been imposed; neither have they the right of appointment to any office, civil or ecclesiastical. The exports to Glasgow and Liverpool are cattle, wool, fish, pig iron, and slates brought from the district of Easdale. A weekly market is held in the town, and two annual fairs. The municipal government of the burgh is vested in two bailies and four councillors; and by its charter the burgesses annually elect a dean of guild, a nominal treasurer, and the different officers connected with a burgh court. The burgh returns, with Ayr, Irvine, Campbelton, and Inverary, a member to parliament. The population of Oban amounted in 1831 to 1480.

OBDORSK, a name which is given to that part of Asiatic Russia which extends along the northern part of the course of the Obi to the Frozen Ocean. It is also the name of a small palisadoed fort, the most northerly of any maintained by Russia, being garrisoned by an officer, with twenty-five Cossacks, who exercise a species of sovereign control over the scattered tribes of Ostiaks and Samoyedes.

OBELISK, in *Architecture*, a truncated, quadrangular, and slender pyramid, raised as an ornament, and frequently charged with inscriptions or hieroglyphics.

Obelisks appear to have been of very great antiquity, and first raised to transmit to posterity certain precepts, which were cut in hieroglyphical characters; but they were afterwards used to immortalize the great actions of heroes, and the memory of persons who were beloved. The first obelisk mentioned in history was that of Ramesses king of Egypt, which was forty cubits high. Phius, another king of Egypt, raised one of fifty-five cubits; and Ptolemy Philadelphus, another of eighty-eight cubits, in memory of Arsinoe. Augustus erected one at Rome in the Campus Martius, which served to mark the hours on a horizontal dial, drawn upon the pavement. They were called by the Egyptian priests the "fingers of the sun," because they were made in Egypt to serve also as styles or gnomons for marking the hours on the ground. The Arabs still call them "Pharaoh's needles." All the learning on the subject of obeliks will be found accumulated in the elaborate work of Zoëga (*De Origine et Usu Obeliscorum*) printed at Rome, and illustrated with very beautiful and accurate plates, in which the hieroglyphics are represented with great distinctness and accuracy.

OBERGLEICHEN, a city of the grand duchy of Saxe-Gotha, in Germany, in the circle of Volkerode, the capital of a bailiwick of the same name. It is situated on the river Ohre, in the Thuringen Forest, and is the property of Prince Hohenlohe of Neuenstein, now mediatized. It contains four churches, two hospitals, 860 houses, and 3640 inhabitants, who carry on various manufactures, especially those of woollen, iron, and copper. Lat. 50. 50. 33. N.

OBERNAY, or OBEREHINHEIM, a town of the department of the Lower Rhine, and the arrondissement of Schletstadt, in France. It stands on the river Ergers, upon the side of the mountain Odilienberg, and contains 4480 inhabitants, who carry on a great trade as coppersmiths and bell-founders.

OBERNIK, a town of the Prussian government of Posen, the capital of a circle of the same name, which contains four towns and 109 villages, with 32,200 inhabitants. It stands on the river Warthe, at its junction with the Welna, and contains 1200 inhabitants, of whom more than one third are Jews. It has some linen weaving.

OBERZO, a city of Austrian Italy, in the province of Milan and delegation of Treviso. It was the *Opitergum* of Strabo, and formerly stood on the sea, but is now some miles from it. It is fortified, and contains 730 houses, with 4560 inhabitants. Long. 12. 24. 49. E. Lat. 45. 46. 23. N.

OBI, a great river of Asiatic Russia, which is said to rise in fifty-two degrees of north latitude, on the southern side of the Altai Mountains, from a lake called by the Tartars Altyn Noor. It is now denominated By, and was formerly known by the name of the Great River, as being the longest which flows through Asiatic Russia. It receives the waters of the Irtysch, after which it becomes very broad, and sometimes extends several miles across. It also spreads out into branches, which again re-unite and form numerous islands. It flows through the governments of Kolivan, Tobolsk, Tomsk, and Narym. The entire length of its stream is two thousand miles; yet, from the northerly course which it takes into the barren and inhospitable regions of Northern Asia, it is comparatively of much less benefit in facilitating the internal communications of the country than if it flowed east and west, as it only gives access to countries cold, unproductive, and barbarous, which mankind would rather desire to fly from than to visit. It abounds, however, in fish, which might become a lucrative object of trade, as during the summer season they might be sent along the Northern Ocean to Archangel.

OBIDOS, a town of Portugal, in the province of Estremadura, and the corregimento of Alenquer. It is situated near the sea coast, on an inlet which forms a small lake called the Lago de Obidos, and contains 1090 houses, but not much more than 3500 inhabitants. On a hill adjoining are the ruins of an ancient castle. A battle was fought at this place by a part of the Duke of Wellington's army, previous to the conflict of Vimiera, in August 1808. It is about forty-five miles north of Lisbon.

OBJECT, in *Philosophy*, is something apprehended or presented to the mind by sensation or imagination. See METAPHYSICS.

OBJECTIVE, is a term used in the schools, in speaking of a thing which exists no otherwise than as an object known. The existence of such a thing is said to be objective.

OBIT signifies a funeral solemnity, or office for the dead, most commonly performed when the corpse lies in the church uninterred; and also the anniversary office. The anniversary of any person's death was called the *obit;* and to observe such day with prayers and alms, or other commemoration, was the keeping of the obit. In religious houses they had a register, in which they entered the obits or obitual days of their founders and benefactors, and which was thence termed the *obituary*. The tenure of obit or chantry lands was taken away and extinguished by 1 Edw. VI. c. 14, and 15 Car. II. c. 9.

OBLATE, flattened or shortened, as an oblate spheroid, having its axis shorter than its middle diameter, and being formed by the rotation of an ellipse about its shorter axis. The earth, the polar diameter of which is shorter than the equatorial, is an oblate spheroid.

OBLATI, in church history, were secular persons, who devoted themselves and their estates to some monastery, into which they were admitted as a kind of lay-brothers. The form of their admission was putting the bell-ropes of the church round their necks, as a mark of servitude. They wore a religious habit, which, however, was different from that of the monks.

OBLIGATION, in general, denotes any act by which a person becomes bound to another to do something, as to pay a sum of money, be surety, or the like. Obligations are of three kinds; natural, civil, and mixed. Natural obligations are entirely founded on natural equity; civil obligations rest on civil authority alone, without any necessary foundation in natural equity; and mixed obligations are those which, being founded on natural equity, are besides enforced by civil authority.

In a legal sense, obligation signifies a bond, in which is contained a penalty, with a condition annexed, for the payment of money, or the performance of some act. The difference between it and a bill is, that the latter is generally without a penalty or condition, though it may be made obligatory; and obligations are sometimes incurred by matter of record, as statutes and recognizances.

OBLIQUE, in *Geometry*, something aslant, or which deviates from the perpendicular. Thus an oblique angle is either an acute or obtuse one, that is, any angle except a right one.

OBLIQUE *Cases*, in *Grammar*, are all the cases of nouns except the nominative.

OBLIQUE *Ascension* is that point of the equinoctial which rises with the centre of the sun, or star, or any other point of the heavens, in an oblique sphere.

OBLIQUE *Circle*, in the stereographic projection, is any circle which is oblique to the plane of projection.

OBLIQUE *Descension*, that point of the equinoctial which sets with the centre of the sun, or star, or any other point of the heavens, in an oblique sphere.

OBLIQUE *Line*, that which, falling on another line, makes oblique angles with it; that is, the one acute, and the other obtuse.

OBLIQUE *Planes*, in *Dialling*, are those which decline from the zenith, or incline towards the horizon.

OBLIQUE *Sailing*, in *Navigation*, is when a ship sails upon some rhumb between the four cardinal points, making an oblique angle with the meridian; in which case she continually changes both latitude and longitude.

OBLIQUUS, in *Anatomy*, a name given to several muscles, particularly in the head, eyes, and abdomen.

OBLONG, in general, denotes a figure the length of which exceeds the breadth; as, for example, a parallelogram.

OBOLUS, an ancient silver money of Athens, the sixth part of a drachma, and worth somewhat more than a penny farthing sterling.

OBOLUS, in *Medicine*, is used to signify a weight of ten grains, or half a scruple.

OBOJAN, a city of Russia, in the government of Kursk, the capital of a circle of the same name. It stands at the mouth of the Obojanta, where that river falls into the Psol, and contains 430 dwelling-houses, with 5500 inhabitants, all trading in the products of the vicinity. It is 756 miles from St Petersburg. Long. 35. 45. E. Lat. 51. 12. N.

OBREPTITIOUS, an appellation given to letters patent, or other instruments, obtained of a superior by surprise, or by concealing from him the truth.

OBSCAIA, a gulf of the Frozen Ocean, on the southern coast of Asiatic Russia, and forming the estuary of the great river Obi. It extends from lat. 66. 40. to 72. 15. N. and from long. 72. to 76. E.

OBSCURE, something that is dark, and reflects little light on material objects, or that is not clear and intelligible in the objects of the intellect.

OBSECRATION, in *Rhetoric*, a figure by which the orator implores the assistance of God or man.

OBSERVATION ISLAND, a small island on the north coast of New Holland, in the Gulf of Carpentaria, on the west shore, and one of Sir Edward Pellew's group.

OBSERVATORY, a place destined for observing the heavenly bodies, being generally a building erected upon some eminence, covered with a terrace for making astronomical observations. There are many such buildings; but the more celebrated are, the Greenwich observatory, built in 1676, by order of Charles II. at the solicitation of Sir Jonas Moore and Sir Christopher Wren, and furnished with accurate instruments; the Paris observatory, built by the order of Louis XIV. in the fauxbourg St Jacques; and Tycho Brahe's observatory, which was situated in the little island of Ween, between the coasts of Schonen and Zealand, in the Baltic. This last was crected and furnished with instruments at the expense of Tycho, and called by him Uraniburg. Here he spent twenty years in observing the stars, the result of which was his catalogue. Pekin observatory Le Compte describes as a magnificent establishment, having been erected and furnished at the intercession of some Jesuit missionaries, principally Verbeist. Of the observatory at Benares, Sir Robert Barker gives a very full account in the Philosophical Transactions (vol. lxvii. p. 598).

OBSERVATORY ISLAND, or PADEVOUA, a small island in the South Pacific Ocean, near the north-east coast of New Caledonia. Long. 165. 41. E. Lat. 20. 18. S.

OBSIDIONALIS, an epithet applied by the Romans to a sort of crown, conferred on those who had distinguished themselves in the attack of fortified places.

OBY, or OUBY, a small island in the Eastern Seas, fifty miles long, and from twelve to twenty broad. The sovereignty of this island is claimed by the sultan of Bachian, who has a pearl fishery on its coasts. On this island live many runaway slaves, who cultivate cloves, which they sell to the Buggesses. The Dutch have a small fort on the western side of the island. Long. 124. 56. E. Lat. 1. 36. S. Little Oby is a small island near the west coast of the above island. Long. 127. 12. E. Lat. 1. 26. S.

OCANA, a town of Spain, in the province of Toledo, the capital of a partida of the same name, about thirty miles to the south-east of Madrid. It stands on a fertile plain, and is surrounded with an ancient and now a dilapidated wall, the buildings bearing more marks of antiquity than of beauty. It has four churches and eleven religious houses, and is adorned with two fountains, one of them of great beauty. The actual population does not much exceed 5000 persons, and the only occupations, besides that of cultivating the surrounding land, consist in making soap, tanning leather, and making a few silk goods. This place has been rendered remarkable by the great battle fought there in November 1809, when the Spanish army of 50,000 was defeated and dispersed by a French force of considerably less than half that number.

OCCIDENT, in *Geography*, the westward quarter of the horizon, or that part of the horizon where the ecliptic, or the sun therein, descends into the lower hemisphere. It it used in contradistinction to *orient*. Hence the word *occidental* signifies any thing belonging to the west; as occidental bezoar, occidental pearl, and the like.

OCCIDENT *Estival*, that point of the horizon where the sun sets at midwinter, when entering the sign Capricorn.

OCCIDENT *Equinoctial*, that point of the horizon where the sun sets when he crosses the equinoctial, or enters the sign of Aries or of Libra.

OCCIPITAL, in *Anatomy*, a term applied to the parts of the occiput, or posterior part of the skull.

OCCULT, something hidden, secret, or invisible. The occult sciences are magic, necromancy, and some others. Occult qualities, in philosophy, were those qualities of body or spirit which baffled the investigation of philosophers, and for which they were unable to give any reason. Unwilling, however, to acknowledge their ignorance, they deceived themselves and the vulgar by an empty title, calling what they did not know *occult*.

OCCULT, in *Geometry*, is used to signify a line that is scarcely perceptible, drawn with the point of the compasses or a leaden pencil. These lines are used in several operations, as the raising of plans, designs of building, and pieces of perspective; and they are to be effaced when the work is finished.

OCCULTATION, in *Astronomy*, the time during which a star or planet is hid from our sight, by the interposition of the body of the moon or some other planet.

OCCUPANCY, in *Law*, is the taking possession of those things which before belonged to nobody. This, according to Blackstone, is the true ground and foundation of all property, or of holding those things in severalty, which by the law of nature, unqualified by that of society, were common to all mankind.

OCEAN, the vast mass of salt water which encompasses all parts of the globe, and by means of which, in the present improved state of navigation, an easy intercourse subsists between places the most distant. The ocean is distinguished into three grand divisions; the Atlantic Ocean, which divides Europe and Africa from America, and is generally about three thousand miles wide; the Pacific Ocean, or South Sea, which divides America from Asia, and is generally about ten thousand miles over; and the Indian Ocean, which separates the East Indies from Africa, and is three thousand miles across. The other seas which are called *oceans* are only parts or branches of these, and usually receive their names from the countries which they border on. See PHYSICAL GEOGRAPHY.

OCEANIDES, in fabulous history, sea-nymphs, daughters of Oceanus, from whom they received their names, and of the goddess Tethys or Thetis.

OCEANUS, in pagan mythology, the son of Cœlus and Terra, the husband of Thetis, and the father of the rivers and fountains. The ancients called him the "father of all things," imagining that he was produced by Humidity, which, according to Thales, was the first principle whence every thing was produced. Homer describes Juno as visiting him at the remotest limits of the earth, and acknowledging him and Thetis as the parents of the gods. He was represented with a bull's head, as an emblem of the rage and bellowing of the ocean when agitated by storms or tempests.

OCELLUS *the* LUCANIAN, an ancient Greek philosopher of the school of Pythagoras, who lived before Plato. His work περι του Παντος, or the Universe, is the only production of his which has come down entire to us; it was written originally in the Doric dialect, but has been translated by another hand into the Attic. William Christian, and after him Louis Nogarola, translated this work into Latin; and there are several editions of it, both in Greek and in Latin.

OCHLOCRACY, that form of government in which the populace have the chief administration of affairs.

OCHRIDA, a town of Greece, in the province of Albania, the capital of a district of the same name, which it has derived from a lake near it, known to the ancients as the Lychnidus. It is situated on the declivity of Mount Maniana Petrin, on the great road formerly leading from Pella to Dyracchium; and near to it runs the river Drino. The inhabitants are descended from a Bulgarian colony, and they adhere to the Greek church, of which religion there is an archbishop in this place. In the vicinity there are mines of sulphur and of silver, the working of which forms the chief occupation of the population, which amounts to about 4500 persons.

OCHUS, a king of Persia, and son of Artaxerxes. He was cruel and avaricious, and, in order to strengthen himself on his throne, murdered all his brothers and sisters. His subjects revolted; but he reduced them to obedience, and added Egypt to his other dominions. Bagoas, his favourite eunuch, poisoned him for the insults which he had offered to Apis, the god of the Egyptians, gave his flesh to be eaten by cats, and caused handles for knives to be made with his bones.

OCKLEY, SIMON, an eminent orientalist, and professor of Arabic in Cambridge, was born at Exeter in 1678. He was educated at Cambridge, and distinguished himself by uncommon skill in the oriental languages. Having taken a degree in divinity, he was, in 1705, presented by Jesus College with the vicarage of Swavesey, and in 1711 he was chosen Arabic professor of the university. He had a large family, and his latter days were rendered unhappy by pecuniary embarrassments. He died in the year 1720. The principal works of Ockley are, 1. Introductio ad Linguas Orientales, a small volume; 2. The History of the Jews throughout the World, from the Italian of Leo Modena; 3. The Improvement of Human Reason, from the Arabic; 4. The History of the Saracens, in 2 vols. 8vo. This last work is justly valued for its accuracy and erudition.

OCKZAKOFF, or OCZAKOW, a city, once of great importance and much historical interest, in European Russia, belonging to the government of Cherson. It stood on the Black Sea, and, from its commanding the navigation of the rivers Bug and Dnieper, it was strongly fortified by the Turks, and considered as an important barrier against the advancing progress of the Russians in that portion of their territory. The citadel connected with the town was of prodigious strength, and surrounded with a wall twenty-five feet in height. It was, however, unable to resist the military force with which the Russians attacked it in 1737. The siege was obstinate, but at length it was taken by assault, after a bloody contest, in which the victorious Russians lost more than 18,000 men. In the following year, the Turks, eager to retake the place, advanced with an army of 70,000 men; but they were repulsed with the loss of more than 20,000 of their number. Having accomplished and secured the conquest, the Russians razed the fortifications, and abandoned the spot. The Turks in 1743 constructed once more the works of defence, and maintained a powerful garrison within it till the year 1788, when the Russians again attacked it. The latter, commanded by Suwaroff, besieged it for a long time, and ultimately carried it by storm, with a tremendous loss of life to both armies. By the peace of 1791, the whole district was ceded to Russia, upon which the fortifications were demolished. The establishment of Odessa within thirty miles of Ockzakoff has reduced the place to insignificance; though, from its position on the two navigable rivers, it is favourably situated for commerce, having good anchorage within the bar of the river Bug. Long. 32. 39. 10. E. Lat. 46. 59. 0. N.

OCRA, a viscous vegetable substance well known in the West Indies, where it is used to thicken soup, particularly pepper pot, as well as for other purposes.

OCRISIA, in fabulous history, the wife of Corniculus, and one of the attendants of Tanaquil, the wife of Tarquinius Priscus.

OCTAETERIS, a cycle or term of eight years, in the Grecian chronology, at the conclusion of which three entire lunar months were added. The cycle was in use till Meton's invention of the golden number or cycle of nineteen years.

OCTAGON, or OCTOGON, in *Geometry*, is a figure of eight sides and angles. When all the sides and angles are equal, it is called a regular octagon, or one that may be inscribed in a circle.

OCTAHEDRON, or OCTAEDRON, in *Geometry*, one of the five regular bodies, consisting of eight equal and equilateral triangles.

OCTANT, the eighth part of a circle.

OCTAPLA, in matters of sacred literature, denotes a Polyglot Bible, consisting of eight columns, and as many different versions of the sacred text.

OCTATEUCH, an appellation given to the first eight books of the Old Testament.

OCTAVE, in *Music*. See INTERVAL.

OCTAVIA, the daughter of Caius Octavius, and sister of Augustus Cæsar. She was one of the most illustrious ladies of ancient Rome, being equally conspicuous for virtue and beauty. The death of Marcellus, her son by her first husband Claudius Marcellus, constantly preyed upon her mind, and she died of grief or melancholy, about eleven years before the Christian era. Her brother paid great honours to her memory, and pronounced her funeral oration. The Roman people also showed their respect for her virtues, by wishing to pay her divine honours.

OCTAVIANUS, or OCTAVIUS CÆSAR, was the nephew of Julius Cæsar the dictator, being the son of Accia, his sister, by Octavius, a senator; and he afterwards became emperor of Rome. He was born in the year of the city 691, during the consulship of Cicero. His uncle Julius Cæsar adopted him, and left him the greater part of his fortune. When he was about twenty years of age he was raised to the consulship. His youth and inexperience were ridiculed by his enemies; but notwithstanding this obstacle, his prudence and valour soon silenced all objections. He made war against his opponents on pretence of avenging the assassination of his uncle, and engaged in five civil contests with success, namely, the wars of Mutina, Perusia, Philippi, Sicily, and Actium; the first and last of which were against M. Antony; the second against L. Antony, brother of the triumvir; the third against Brutus and Cassius; and the fourth against Sextus Pompey, son of Pompey the Great. He united his forces with those of Antony at the battle of Philippi; and had he not been supported by the activity and bravery of his colleague, he would doubtless have been totally ruined in that engagement. In his triumvirate with Antony and Lepidus, he obtained the western parts of the Roman empire; and, like his other colleagues, the more firmly to establish his power, he proscribed his enemies and cut them off. The triumvirate lasted for ten years. He had given his sister Octavia in marriage to Antony, to render their alliance more lasting; but when Cleopatra had charmed this unfortunate man, Octavia was repudiated. Augustus immediately took up arms to avenge the wrongs of his sister, but perhaps more from a desire to remove a man whose power and consequence kept him in continual fear and constant dependence. Both parties met at Actium to decide the fate of Rome. Antony was supported by all the power of the East, and Augustus by that of Italy. Cleopatra fled from the battle with sixty ships; and her flight ruined the interest of Antony, who followed her into Egypt. The conqueror soon afterwards proceeded to Egypt, where he besieged Alexandria, and honoured with a magnificent funeral his unfortunate colleague and the celebrated queen, whom the fear of being led in the victor's triumph at Rome had driven to commit suicide. After he had established peace all over the world, he shut the gates of the temple of Janus in the year of the city 753. He twice determined to lay down the supreme power, first immediately after the victory obtained over Antony, and again on account of his ill health; but his two faithful friends Mecænas and Agrippa dissuaded him, and contended that if he did he would leave it a prey to the most powerful, and besides expose himself to the greatest dangers. He died at Nola in the seventy-sixth year of his age, after he had held the sovereign power during fifty-seven years. He married four times, but he was unhappy in all these connexions; and his only daughter Julia disgraced herself and her father by the debauchery and licentiousness of her manners. At his death he recommended his adopted son Tiberius as his successor. He left his fortune partly to him and to Drusus, and made donations to the army and Roman people. The title of Augustus was conferred upon him by the senate after the battle of Actium and the final destruction of the Roman republic. The title continued afterwards, being given to his successors in the empire. Virgil is said to have written his Æneid at the desire of Augustus, whom he represents under the amiable and perfect character of Æneas.

OCTOBER, in *Chronology*, the eighth month of Romulus's year, as the name implies; but the tenth in the calendar of Numa, Julius Cæsar, &c. The senate gave this month the name of *Faustinus*, in compliment to Faustina, the wife of the Emperor Antoninus; Commodus wished it to be called *Invictus;* and Domitian named it *Domitianus;* but in spite of all these attempts it still retains its original name. This month was sacred to Mars, and under his protection.

October *Equus*, a horse annually sacrificed to Mars in the month of October, either because the horse is a warlike animal, or in order to punish him for the taking of Troy. A race was run with chariots, drawn by two horses, previously to the sacrifices, and he that ran fastest was adjudged to be the victim.

OCTOSTYLE, in the ancient architecture, is the face of an edifice adorned with eight columns.

ODDLY Odd. A number is said to be oddly odd when an odd number measures it by an odd number. Thus 15 is a number oddly odd, because the odd number 3 measures it by the odd number 5.

ODE, in *Poetry*, is a song or composition proper to be sung.

ODENATUS, a celebrated prince of Palmyra, who very early inured himself to bear fatigues, and, by hunting leopards and wild beasts, accustomed himself to the labours of a military life. He was a faithful friend to the Romans; and when Aurelian had been taken prisoner by Sapor king of Persia, Odenatus warmly interested himself in his cause, and solicited his release, by writing to the conqueror, and by sending him presents. The king of Persia was offended at this liberty of Odenatus; he tore the letter, and ordered the presents which were offered to be thrown into a river; and to punish Odenatus, who had the impudence, as he called it, to pay homage to so great a monarch as himself, he commanded him to appear before him, on pain of being devoted to instant destruction with all his family if he dared to refuse. But Odenatus despised the haughty summons of Sapor, and opposing force by force, obtained some considerable advantages over the troops of the Persian king, took his wife prisoner, and, besides, obtained a great and rich booty. These services were observed with gratitude by the Romans; and Gallienus, then emperor, named Odenatus his colleague on the throne, and gave the title of Augustus to his children, and to his wife the celebrated Zenobia. Odenatus, invested with new power, resolved to signalize himself more conspicuously, by conquering the barbarians of the north; but he perished by the dagger of one of his own relations, whom he had slightly offended at a domestic entertainment. He died at Emessa, about the 267th year of the Christian era. Zenobia succeeded to his titles and honours.

ODENSEE, a city of Denmark, the capital of the island of Funen. It is situated on a canal connecting it with a lake, and in connection with the sea in the Gulf of Stegestrand. It is tolerably built, with good streets, and has a cathedral and seven other churches. It contains about 800 houses, with 6500 inhabitants, who are chiefly engaged in internal trade. Long. 11. 20. 4. E. Lat. 55. 23. 35. N.

ODER, a river of Germany, which has its source near a town of the same name in Silesia, and upon the confines of Moravia. It runs northward through that province, and then into the marche of Brandenburg and Pomerania, where it forms a large lake, and afterwards falls into the Baltic Sea by three mouths, between which lie the islands of Usedom and Wolin. It passes by several towns, as Ratibor, Oppeln, Breslau, Glogau, and Grossen, in Silesia; Francfort, Lebus, and Custrin, in Brandenburg; and Gartz, Stettin, Cammin, Wallin, Usedom, and Wolgast, in Pomerania.

ODESSA, a city of Russia in Europe, within the circle of Tiraspol, in the government of Cherson. It owes its present state, and the rapid advance it has made, to its position on the north-western shore of the Black Sea, between the mouths of two great rivers, the Dniester and the Dnieper, and being not more than twenty-four miles from the Bug, which is navigable from Poland.

From the reign of Peter the Great, Russia had been steadily looking forward to a maritime preponderance, both military and commercial, on the Black Sea; and soon after the peace of Oczakow, by which the province of Cherson was ceded to Catharine, that princess selected as the place for a commercial emporium a village called Kodschabey, then inhabited only by a few fishermen. At first several regiments were marched to the spot, and the erections of public buildings commenced. The first civil settlers were a number of Greek families, who were induced to remove thither from other portions of the country which had been recently given up by the Turks. When the Emperor Alexander ascended the throne, he entered with zeal into the project which Catharine had formed. The French emigrant Duke of Richelieu, who had entered the Russian service, was appointed governor, and displayed great zeal and judgment. By an imperial ukase, all taxes were suspended for sixty years; in consequence of which a considerable number of persons were induced to fix themselves in Odessa, so that by the year 1804 the inhabitants had increased to 15,000. With the progress of population that of public buildings kept pace. A fortress, a lighthouse, and a lazaretto, were constructed, as well as a mole to secure 300 sail of vessels from the south-west winds, which sometimes blow with prodigious force. The war between Russia and Turkey, which was terminated by the general European peace on the capture of Paris, had impeded till that event the growth of the city; but soon afterwards the port of Odessa was declared to be an open one. All goods of every kind could be imported without duty for the consumption of the city, or for re-exportation, but were chargeable with duty on passing into the surrounding country. This gave a great impetus to its advancement, which still operates, till the population has increased to nearly 50,000 persons. The inhabitants, as is natural in new settlements, are of very mixed races. The chief part of them consists of Russians, Greeks, and Jews; but German handicraftsmen are found amongst them in considerable numbers, whilst the more extensive mercantile houses are composed of Italians, English, French, or Armenians. In no spot perhaps in Europe are there so great a number of languages spoken as on the exchange of Odessa. The admixture of oriental dresses, manners, and languages, presents a very novel and lively picture. A stranger might imagine himself translated into one of the trading towns of the Levant; for the bazaars contain all the productions of the East, from Persian shawls down to rose-pastilles; and the Italian language is universally understood.

The prosperity of Odessa has risen in a great measure from its maritime accessibility. It has a spacious bay, Odessa. which, though open to the easterly winds, is tolerably secure; it is very extensive, and the anchorage ground is good. There is a kind of harbour formed by two moles, about two thirds of a mile in length, and a handsome quay capable of receiving vessels of 500 tons burden. The situation of the town on the shore, the land rising very gradually, gives it a good appearance on approaching it from the sea. Like most new places, it is regularly built; the streets are wide and straight, crossing each other at right angles; and the houses are for the most part built of stone, and two stories in height. The streets are however unpaved, and consequently in rainy weather present a mass of mud and dirt; and, on the other hand, when the weather is dry, the clouds of sand which arise prove a terrible annoyance. The place is defended by a strong citadel on the north-east, which has a double ditch, and also several outworks. The walls that surround the city are of more use in a financial than a military point of view. Amongst the public edifices, the most conspicuous is the cathedral, a large and elegant pile. There are eight other churches for the Greek worship, some belonging to the orthodox faith, and others to schismatics. The Jews, Roman Catholics, and German Lutherans, have their respective places of worship. A college has been established, with a museum and botanic garden. There is a large hospital, an assembly room, and a theatre, where plays are performed alternately in the Russian and Greek language, and which is sometimes used for the performance of Italian operas. There are several institutions for educating the poorer classes of both sexes; those for females being under the superintendence of the wife of the governor of the province, who resides here. Most of the water is brackish, and to provide that necessary element in purity, an aqueduct has been constructed, at an expense of more than a million roubles, which conveys it from a distance of nearly twenty miles. All the absolute necessaries of life are remarkably cheap, as must be the case where a single town draws its supplies from a vast and fruitful plain like that which surrounds this city on the land side.

As the rapid growth of Odessa, and the prospect of its continued and increasing extent, depend wholly upon its commerce, it is desirable to take a view of the sources of that commerce. These are to be found in the fertility of its surrounding soil, and that of the more distant districts, to which there is easy access. The steppes, which form a semicircle around Odessa, being the *Sors Deserta* of the ancients, extend to nearly 100 miles from the city. This district is destitute of trees and of water, but the soil is said to be favourable to the growth of corn, especially of wheat. From February to May the growth of grass is most luxuriant, so that it is said to become so high as to hide the cattle; but in the latter month it begins to wither, and in the summer the land is so totally deprived of all verdure, as to present the picture of a dry sand-bank on the sea-shore. The first rains of autumn cause vegetation to shoot forth again with rapidity, till it is checked by the sharp frosts, sometimes of November, but more commonly of December. The slight attempts which have been made to cultivate this portion of land have for the most part been abandoned, and the labour of the residents has been chiefly applied to the feeding and propagating of sheep, and that more for the sake of the wool than of the flesh.

It is from districts bordering upon the northern side of the steppes that the land is to be found, the soil of which, even with the negligent husbandry it receives, is the most abundantly productive of wheat. Whether from the climate or the soil, or from the combination of both, or from other causes of which we are ignorant, there is no part of the world known in which, in propitious seasons, the increase of that grain is so great It is, however, liable to great variations in its growth, and sometimes years occur when the increase is very insignificant.

There are two kinds of wheat cultivated in the district, distinguished by the properties of the hardness or the softness of the grain. They are both white. The hard wheat is most proper for the countries bordered by the Mediterranean Sea, where it is not ground in mills, but is pounded in mortars, and used as food under the names of macaroni, vermicelli, and other similar preparations, which are eaten in those countries as a substitute for bread. The soft wheat comes from the most distant parts. It is the same as that grown in Poland, and brought to England sometimes by way of Dantzic, and occasionally by way of Odessa, and is, by grinding, converted into excellent flour. The hard wheat is sown in the spring of the year, and ripens almost as speedily as barley. The soft wheat is sown in October or November, before the frost sets in, and both ripen nearly together. The extent sown is in some measure regulated by the intelligence received of the productiveness of the preceding harvest in the several countries of Europe. If an extensive failure in the west of Europe is known to have occurred, the intelligence must arrive too late for any great extent of additional land being sown with winter or soft wheat; but as soon as the frost ceases, great activity in the labours of the field is applied to the preparation of the land, for the reception of the seed of spring or hard wheat. Thus the proportion which the two kinds of wheat bear to each other varies with the state of the annual product in those remote countries which draw their supplies from the Black Sea.

The greater portion of the wheat comes from a distance of 200 miles, some of it 250 miles; and in years when the demand is very great, a portion is brought even a distance of 400. A part of it is sent by the growers, or by merchants who have purchased of them, to be sold by the commission-houses in Odessa; but in some seasons large contracts are entered into for the wheat by Odessa merchants at a fair, to which sellers and buyers resort in great numbers, and which is held at the city of Kiew, from the 15th to the 25th of January in each year. The contracts are made for the corn to be delivered on shipboard by the sellers at their own expense, and the money to be paid on delivery; but it has occurred, in seasons when a very great demand was expected, as in 1817, that money has been advanced beforehand on the credit of the future delivery.

The wheat is brought in small waggons, drawn by two bullocks, and the number arriving in Odessa in one day has sometimes amounted to 500 or 600, and in several instances to 1000. Each of these waggons conveys eight sacks of wheat, and the whole load is three quarters and a half, weighing about 1700 pounds. They are dragged along at the rate of about ten miles a day. Though the cattle are grazed free of expense, on the pasture-land on the way, except over the steppes, where, in the months from May to July, the greatest periods of shipment, there are no vestiges of vegetation, the expense is still so considerable, that it has been often found to amount, when the prices have been low, to as much, and in some instances to even more, than the load would sell for at Odessa; and that, too, although the value of a day's labour for a man and two bullocks is only sixpence in Podolia, the province from which most of the wheat is brought.

The wheat is not dried before shipping at Odessa, as is done at Dantzic, and is, therefore, not well calculated for a long sea voyage, when, from heating, it becomes spoiled This has been the case with cargoes sent to London, where, on its arrival, the grain has so run together as to be utterly unfit for food, and has been dug out with pick-axes and thrown into the Thames. The principal portion of the wheat from Odessa is sent thence to Constantinople, Malta, and the ports of Italy, France, and other dépôts in the Mediterranean. It is there often a substitute for wheat grown near them; and when this grain is scarce in England, and other distant markets, the produce of their own harvests is exported. The following table will show the fluctuations in the exports.

An Account of the Quantities of Wheat exported from Odessa in each Year from 1814 to 1836, *from consular returns.*

1814	187,685 quarters.
1815	372,309 ...
1816	801,591 ...
1817	870,893 ...
1818	538,513 ...
1819	627,926 ...
1820	534,199 ...
1821	435,305 ...
1822	342,752 ...
1823	443,035 ...
1824	427,767 ...
1825	170,370 ...
1826	Little or no demand, freights high, and no ships to be had.
1827	No trade in corn; all affairs suspended, from the state of public matters in Constantinople.
1828	Trade suspended by the war with Turkey.
1829	No trade in corn this year.
1830	149,209 quarters. All exported in the last three months of the year, when peace was concluded.
1831	No returns.
1832	401,981 quarters.
1833	101,000 quarters. All exported in the first three months of the year.
1834	45,000 quarters. Crops partially failed.
1835	283,575 ...
1836	452,714 ...

The variations in price during this series of years were excessive. Thus the average price of the year 1825, which was the lowest, was only 13s. 6d. the English quarter; and the average price of the year 1817, which was the highest, was 49s. 11d., being fluctuations to the extent of 375 per cent. The excessive fluctuations in the price, as well as the quantity of the exports, have had a great influence on the prosperity of the city, the chief export consisting of a single article. In the year 1817, the wheat shipped at Odessa was 870,893, at an average of 50s. the quarter, and thus amounting to L.2,177,232. The quantity shipped in 1825 was 170,370, at 13s. 6d. the quarter, thus amounting to no more than L.115,100. It is natural to suppose that a declension in the amount of a single article of exportable produce, to the extent of more than nineteen parts in twenty of its value, must have caused a great convulsion amongst the mercantile establishments at Odessa; and accordingly, in the eight years from 1817 to 1825, almost the whole of them were reduced to a state of insolvency. As regards the producers of the article in question, they too suffered severely. The high prices obtained in 1816 and 1817 gave an impulse to agriculture, which induced the proprietors of land to apply to its cultivation whatever capital they could obtain, either by their own credit, or by mortgaging their estates. The latter was effected with great facility, and to an extent which was severely felt for a long period by the larger proprietors. Many of the small cultivators, who occupied land belonging to the crown, on long leases, with neither rent nor taxes to pay for the first twenty-five years, were induced, by the low prices of wheat, to abandon their holdings, and to repair to the city, where they could obtain employment in the commonest kind of labour, with a better reward than cultivation yielded. Experience has taught the inhabitants the very fluctuating state of the commerce of wheat, and at length many of them have applied their capital and their industry to the cultivation of other articles. The soil is found to be highly favourable to the growth of flax, but more especially to hemp; and large quantities of both are now raised. The breeding of black cattle has also been much extended, and creates a large export of hides and tallow. The tallow shipped increased between the years 1816 and 1831, from the value of 100,000 roubles to that of 2,000,000. Large flocks of sheep have also been reared, and the ancient breeds in many cases have been so effectually crossed by sheep of the Merino race, that much wool of an improved and still improving quality is despatched to Italy, France, England, and Germany. The old commercial houses, who had been ruined by the great depreciation in the price of wheat subsequently to 1817, have been replaced by new firms from Russia, Italy, Germany, France, and England, furnished with ample capital and credit. Some manufactures have been established, which yield a surplus of sail-cloth, cordage, and soap. The value of the exports, since the decline in the wheat trade, has more than doubled during the last ten years. The imports consist for the most part of coffee, sugar, olive-oil, cotton wool, wine, cotton, silk, and woollen goods, timber, coals, fruit, dye-stuffs, tea, and hardware. Odessa has also become a dépôt for an increasing trade with the ports of Asia on the Black Sea.

The number of vessels, and the flags they bore, that entered Odessa in the course of six years, were—

Austrian	953	French	17
Russian	732	Swedish	11
Sardinian	675	Spanish	8
British	598	Dutch	7
Greek	81	Tuscan	3
Turkish	32	American	2
Neapolitan	25		

The tonnage of these is not known; but as the Austrian and Russian vessels must have chiefly consisted of coasters from the ports of these nations within the Black Sea, it is probable they were of much lighter burden than the vessels of the other nations which had come through the Bosphorus. The vessels under the British flag belonged mostly to Malta and the Ionian Islands. The situation of Odessa is in latitude 46. 28. 54. north, and longitude 30. 43. 22. east. The climate is healthy, and the winter, though short, is severe, the sea being more or less frozen for about two months. The summer is intensely hot, but it is deemed salubrious.

ODEUM, in Grecian antiquity, a theatre for music built by Pericles, the inside of which was filled with seats and ranges of pillars, and on the outside the roof descended shelving downwards from a point in the centre, with many bendings, in imitation of the king of Persia's pavilion. Here the musical prizes were contended for; and here, also, according to Aristophanes, there was a tribunal.

ODIHAM, a market-town of the county of Hants, in the hundred of its own name, forty-two miles from London, and twenty-four from Winchester. It has a market, which is held on Saturday, and but little trade except what arises from its wharf on the Basingstoke Canal. A mile from it are the remains of an ancient castle, in which David king of Scotland is said to have been kept a prisoner. The population amounted in 1801 to 1058, in 1811 to 1104, in 1821 to 2423, and in 1831 to 2647.

ODIN, in *Mythology*, called also, in the dialect of the Anglo-Saxons, *Woden* or *Wodan*, a name given by the ancient Scythians to their supreme god, and assumed, about seventy years before the Christian era, by Sigge, a Scythian prince, who conquered the northern nations, made great changes in their government, manners, religion, and had even divine honours paid him. According to the account given of this conqueror by Snorro, the ancient historian of Norway, and his commentator Torfæus, Odin was a Scythian, who withdrew himself by flight, along with many others in his train, from the vengeance of the Romans, under the conduct of Pompey; and having officiated as a priest in his own country, he assumed the direction of the religious worship as well as the civil government of the nations which he had conquered. Having subdued Denmark, Sweden, and Norway, he retired to Sweden, where he died. There is nothing certain in this account; but it is probable that the god whose prophet or priest this Scythian pretended to be, was named Odin, and that the ignorance of succeeding ages confounded the deity with his priest, composing out of the attributes of the one and the history of the other the character of the northern conqueror. He deluded the people by his enchantments and his skill in magic. Having cut off the head of one Mimer, who in his lifetime enjoyed great reputation for wisdom, he caused it to be embalmed, and persuaded the Scandinavians that he had restored it to the use of speech, and caused it to pronounce whatever oracles he wanted. The Icelandic chronicles or sagas represent Odin as the most eloquent and persuasive of men; they ascribe to him the introduction of the art of poetry amongst the Scandinavians, and likewise the invention of the Runic characters. He had also the address to persuade his followers that he could run over the world in the twinkling of an eye; that he had the direction of the air and the tempests; that he could transform himself into all sorts of shapes, raise the dead, foretell things to come, deprive his enemies by enchantment of health and vigour, and discover all the treasures which were concealed in the earth. They add, that by his tender and melodious airs he could make the plains and mountains open and expand with delight; and that the ghosts, thus attracted, would leave their infernal caverns, and stand motionless about him. Nor was he less dreadful and furious in battle; changing himself into the shape of a bear, a wild bull, or a lion, and amidst ranks of enemies committing the most horrid devastation, without receiving any wound in return.

ODOACER, according to Ennodius, was meanly born, and only a private man in the guards of the Emperor Augustulus, when, in the year 476, under the consulship of Basilicus and Armatus, the barbarians chose him for their leader. The barbarians thought that, as they often defended Italy, they had a right to at least part of it; but upon demanding this they were refused, and the consequence was a revolt. Odoacer is said to have been a man of uncommon parts, capable alike of commanding an army or of governing a state. Having left his own country when he was very young, to serve in Italy, he was admitted amongst the emperor's guards, and continued in that station till the above year; when, putting himself at the head of the barbarians in the Roman pay, who, although of different nations, had unanimously chosen him to be their leader, he marched against Orestes, and his son Augustulus, who still refused to share any of the lands in Italy. The Romans were inferior both in numbers and in valour, and were, therefore, easily conquered. Orestes was ordered to be slain; but the Emperor Augustulus was spared, and, although stripped of his dignity, was treated with humanity, and allowed a liberal sum for his own support and for that of his relations. Odoacer was proclaimed king of Italy, but assumed neither the purple nor any other mark of imperial consequence. He was afterwards defeated and slain by Theodoric the Ostrogoth.

ODOMETER, an instrument used for measuring the distance passed over in travelling.

ODOROUS, or ODORIFEROUS, appellations given to whatever smells strongly, whether they be fetid or agreeable, but chiefly to things the smell of which is brisk and pleasant.

ŒCONOMICS, the art of managing the affairs of a family or community; and hence the person who takes care of the revenues and other affairs of churches, monasteries, and the like, is termed *œconomus*.

ŒCUMENICAL signifies the same with *general* or *universal;* as, œcumenical council, bishop, and the like.

OEDENBURG, a city of the Austrian kingdom of Hungary, in the province of the Farther Danube. It is the capital of a circle of the same name (called also Soprony-Barmegye in Hungarian), which extends over 1269 square miles, and comprehends three cities, forty-one market-towns, and 200 villages, with 185,700 inhabitants. It stands on the river Ikva, and is a well-built town, with one Lutheran and two Catholic churches, a monastery and a nunnery, 820 houses, and 12,650 inhabitants, of whom about 5000 are Protestants. It is an industrious place, with manufactures of cotton, woollen, silk, and linen goods, besides glass-houses, sugar refineries, and iron forges; and the neighbourhood yields some good wine. Long. 17. 28. 11. E. Lat. 47. 40. 36. N.

ŒDIPUS, an unfortunate king of Thebes, whose history is partly fabulous. He flourished about 1266 before Christ. It is said he was given by his father to a shepherd, who was ordered to put him to death, in order to prevent the misfortunes with which he was threatened by an oracle. But the shepherd, being unwilling to kill him with his own hands, tied him by the feet to a tree, that he might be devoured by wild beasts. The infant was however found in this situation by another shepherd named Phorbas, who carried him to Polybus king of Corinth, whose queen, having no children, educated him with as much care as if he had been her own son. When he had grown up, he was informed that he was not the son of Polybus; upon which, by order of the oracle, he went to seek for his father in Phocis; but scarcely had he arrived in that country when he met his father on the road, and killed him without knowing him. A short time afterwards, having delivered the country from the monster called the *Sphinx*, he married Jocasta, without knowing that she was his mother, and had four children by her; but afterwards, being informed of his incest, he quitted the throne, and, thinking himself unworthy of the light, put out his eyes. Eteocles and Polynices, both celebrated amongst the Greeks, were the issue of this incestuous marriage.

OEGWA, a town on the Gold Coast of Africa, situated upon the brow of an eminence, which rises by a gentle ascent to a considerable height, and is defended by rocks, against which the waves beat with the utmost violence.

OEHRINGEN, a city of the kingdom of Wirtemberg, in the circle of the Jaxt, the capital of a bailiwick of the same name, in the territories of the mediatized Prince of Hohenlohe-Oehringen. It stands on the river Ohra, is the residence of the prince, and contains, besides the palace, 480 houses, with 3327 inhabitants, who are occupied in making jewellery and gold and silver articles, also in the cotton manufacture, and in growing wine.

OELAND, or OLAND, an island in the Baltic Sea, a part of the province of Calmar, in Sweden. It is about seventy miles in length from north to south, and about seven miles in breadth from east to west. The western side is flat, and the eastern rather hilly; but the centre is a level consisting of tolerably good soil, which yields barley, rye, and oats, and, from the mildness of the climate, brings the harvest two weeks earlier than on the opposite continent. It has some good pastures, which furnish dairies; and a considerable fishery is carried on upon the coast. It contains no market-town, but has eight parishes, and 24,000 inhabitants.

OELS, a circle of the Prussian province of Silesia, which has become remarkable on account of its having been bestowed on the Duke of Brunswick when expelled from his hereditary dominions by Bonaparte. It was formerly a sovereignty, but is now mediatized; and the ancient race of its dukes has become extinct. It extends over 814 square miles, and contains nine cities and towns, 344 villages, and 164 hamlets, inhabited by about 95,000 persons. The chief place is the city of the same name situated on the river Oelse, which runs to the Weyda in its course to the Oder. It is surrounded with walls, and contains one Catholic and five Lutheran churches, 480 houses, and about 5000 inhabitants. In the ancient castle of the dukes is a numerous library and a cabinet of natural history. The chief employment of the inhabitants is in the linen trade.

ŒNOPTÆ, in Grecian antiquity, a kind of censors at Athens, who regulated entertainments, and took care that none drank too much or too little.

ŒREBRO, one of the provinces of the kingdom of Sweden, being the westernmost part of Westmanland. It extends in north latitude from 58. 40. to 60. 6. and in east longitude from 14. 6. to 15. 42., and contains a superficies of 3784 square miles. It is divided into four districts or bailiwicks, viz. Osterwick, Westrericke, Nora cum Linne, and Leke cum Carlscrona, and contains 110,000 inhabitants. It is surrounded with mountains, but none of them higher than 2000 feet, and the interior is flat or undulating. It is an internal province, but connected with Stockholm by means of the river Heilmaren. It contains a great number of fresh-water lakes. The climate is raw and cold, but in the short summer vegetation is surprisingly rapid. The best agriculture is in the southern part, but there the seed rarely produces more than four-fold. The chief grains are rye, oats, and barley; and of late potatoes and turnips have been introduced. The chief production is timber, and the cutting and preparing of it for market is the principal occupation. There are some mines of iron and of copper worked. The capital is the city of the same name, situated at the entrance of the river Svartelf into the Heilmaren. It is chiefly built of wood, has a good market, a church, and an hospital, and contains 750 dwellings, with 3240 inhabitants, a few of whom are employed in making cloths, hosiery, and ironmongery articles. Long. 15. 4. 5. E. Lat. 59. 15. 14. N.

ŒTA, in *Ancient Geography*, a mountain of Thessaly, extending from Thermopylæ westward to the Sinus Ambracicus, and in some measure cutting at right angles the mountainous country stretching between Parnassus to the south and Pindus to the north.

OETTINGEN, a city of the kingdom of Bavaria, in the circle of the Rezat, which, with a district around it of seventy square miles and 12,500 inhabitants, forms a bailiwick belonging to the mediatized Prince of Oettingen-Oettingen. The city is the residence of the prince. It stands on the river Wernitz, is well built, and contains a Catholic and a Lutheran church, 460 houses, with 3480 inhabitants, who are chiefly employed in making linen and cotton goods. Long. 10. 31. 5. E. Lat. 48. 57. 27. N.

OFFENBACH, a city of the grand duchy of Hesse, in Germany, in the province of Darmstadt, and the capital of a bailiwick of the same name. It stands on the river Maine, and is well built, being on one side surrounded with a wall, and on the other with a ditch. It contains 530 houses, with 6950 inhabitants, who are chiefly occupied in making iron and hardware, and a variety of ornamental articles of steel, silver, and gold.

OFFERINGS. Amongst the Hebrews there were several kinds of offerings, which they presented at the temple. Some were free-will offerings, and others were offerings of obligation. The first fruits, the tenths, and the sin-offerings, were of obligation; the peace-offerings, vows, offerings of wine, oil, bread, salt, and other things, which were made to the temple or to the ministers of the Lord, were offerings of devotion. The Hebrews called offerings in general *corban*. But the offerings of bread, salt, fruits, and liquors, as wine and oil, which were presented at the temple, they termed *mincha*. The sacrifices are not properly offerings, nor are they commonly included under that name.

OFFICIAL, in the canon law, an ecclesiastical judge, appointed by a bishop, chapter, or abbot, with charge of the spiritual jurisdiction of the diocese.

OFFICIAL is also a deputy appointed by an archdeacon as his assistant, and who sits as judge in the archdeacon's court.

OFFICINAL, in *Pharmacy*, an appellation given to such medicines, whether simple or compound, as are required to be constantly kept in the apothecaries' shops.

OFFING, or OFFIN, in nautical language, that part of the sea a good distance from shore, where there is deep water, and no need of a pilot to conduct the ship. Thus, if a ship from shore be seen sailing out to seaward, they say, "she stands for the offing;" and if a ship, having the shore near her, have another a good way without or beyond her, towards the sea, they say, "that ship is in the offing."

OGHAMS, a particular kind of stenography, or writing in cipher, which was practised by the Irish. Of these there were three kinds. The first was composed of certain lines and marks, which derived their power from their situation and position, as they stood in relation to one principal line, over or under which they were placed, or through which they were drawn. The principal line was horizontal, and served for a rule or guide, the upper part of which was called the left, and the under side the right; above, under, and through which line, the characters or marks were drawn, that stood in the place of vowels, consonants, diphthongs, and triphthongs.

OGIVE, in *Architecture*, an arch or branch of a Gothic vault, which, instead of being circular, passes diagonally from one angle to another, and forms a cross with the other arches. The middle, where the ogives cross each other, is called the *key*, being cut in the form of a rose, or a *cul de lampe*. The members or mouldings of the ogives are called *nerves*, *branches*, or *reins*; and the arches which separate the ogives, *double arches*.

OGYGES, king of the Thebans, or, according to others, of Ogygia and Actæ, afterwards called Bœotia and Attica. He is recorded to have been the first founder of Thebes and Eleusis. The famous deluge happened in his time, in which some say he perished, along with all his subjects, 1796 before our era.

OHANG JAVA, a cluster of islands in the Pacific Ocean, discovered by Tasman. Most of them are little better than large rocks. Lat. 4. 36. N.

OHETEROA, an island about twelve miles in circumference, in the South Pacific Ocean, without either harbour or anchorage, and only a foul and rocky bay on the west coast. The inhabitants are active, well made, and of a dark complexion. They form circles round their arms and legs, but have no figures on the other parts of their body. Their clothing is made of the bark of a tree, and is curiously coloured; and some of them wear bonnets, adorned with feathers, whilst others wear white stuff in the form of a turban. Their arms are lances made of very hard wood, and long pikes. This island was first discovered by Captain Cook in the year 1769. It is well inhabited, though it is not twenty miles in circumference. It has not, like the Society Islands, any coral reef surrounding it. Long. 150. 47. W. Lat. 22. 27. S.

OHEVAHOA, a steep and craggy island in the Southern Pacific Ocean, about fifteen leagues in circumference. Its deep valleys, and the sides of its hills, are clothed with trees and with verdure. It is situated in long. 139. 2. W. and lat. 9. 42. S.

OHIO, one of the principal states in the North American union, is situated between 38. 30. and 42. 0. of north la-

Ohio. titude, and between 80. 28. and 84. 42. longitude west from Greenwich. On the north it is bounded by Michigan and Lake Erie; on the east by Pennsylvania and the river Ohio; on the south by the Ohio River, which separates it from Virginia and Kentucky; and on the west by Indiana. Ohio may extend about 220 miles from north to south, and as much from east to west; but as Lake Erie projects considerably into the northern borders, and the Ohio cuts off much of its southern quarter, the area of the state cannot be computed at more than 200 miles square. Ohio occupies about one third of the plane which declines from Pennsylvania to the Mississippi, and may be considered generally as a surface of table-land, sloping in one direction towards the Ohio, and in the other towards Lake Erie. The state is divided by nature into four grand divisions, which are named after the principal waters on which they are situated. These are the Miami country, the Scioto country, the Muskingum country, and the Lake country. The interior and northern parts of Ohio are generally level, but the northern belt has large tracts of wet and marshy soil. They are however placed in such positions as render them easily drained; and when they are cleared of the forests which cover them, they will form not the least valuable parts of the state. In its primitive condition, Ohio was, with the exception of some central prairies, overspread with a dense forest, to which the great fertility of the soil gave a stupendous development; indeed the size, majesty, and variety of the trees of the Ohio basin has been a theme of just admiration. There are still extensive tracts of land heavily timbered, and which are as level as prairies. The forest-trees are the same as those of Kentucky and Indiana, excepting that the peccan tree, which is common on the waters of the Wabash, is seldom found here. The forests are deep, and some of them are in the richest soils, where, however, the trees are less remarkable for their size than for their straightness. On the head waters of the two Miamis, the Muskingum, and the Scioto, there are rich and extensive prairies, some of which are low and marshy, and others are elevated and dry, the latter being by no means so fertile as the former. Immediately on the borders of the Ohio, there are numerous tracts of intervale or meadow-land of exuberant fertility. In the interior parts, bordering on both sides of the Scioto, and on the two Miamis, are the most extensive tracts of rich and level land. About one quarter of the eastern and south-eastern divisions of Ohio is hilly, in some places too broken and precipitous to admit of cultivation; but in no parts are the hills very large or high, and nine tenths of the surface of the state are susceptible of cultivation. "On its whole wide surface," says Mr Flint, "there is scarcely any land so hilly, sterile, or marshy, as, with moderate labour, may not be subdued, drained, or cultivated. The whole region seems to have invited a hardy and numerous body of freeholders to select themselves moderate and nearly equal-sized farms, and to intersperse them over its surface. In respect to the smallness of the farms, the number, equality, and compactness of the population, not confined, as farther west, to the water-courses, but diffused over the whole state, it compares very accurately with New England."

Rivers. The principal river of Ohio is the noble and beautiful stream to which it owes its name; but this will demand a separate notice. The next largest and most interesting river in this state is the Great Miami, which rises between 40 and 41 degrees of north latitude, and interlocks with the Massissineway of the Wabash, and the St Mary's and Au Glaize, branches of the Maumee and Scioto. It has a south-westerly course of above fifty miles, flowing in a strong but generally smooth and unbroken current, through a valley of uncommon width and fertility, receiving several tributaries in its course. The Little Miami rises in the south-west corner of Madison county, and, after traversing several counties, joins the Ohio seven miles above Cincinnati. It is of little importance as a navigable stream; but it is valuable in a manufacturing point of view, there being upwards of sixty mills upon it. It has a number of branches; and about one hundred miles from its mouth it forms singular rapids, the stream being compressed to ten yards in width, and falling two hundred feet within no great distance. The country between the Great and Little Miami is in general finely watered, healthy, pleasant, and fertile, and may be characterised as the garden of the state. The Scioto is a considerable river of Ohio, and has the whole of its course in the state, being little short of two hundred miles, one hundred and thirty of which are navigable. It rises in a morass north of Logan county, in the southern division of the state, and has generally a south-easterly course. The banks of the Scioto now rank amongst the most fertile, eligible, and pleasant parts of the state. Between this river and the Muskingum is situated the great Hockhocking and its waters. It has a deep and still but narrow channel, and is navigable for boats forty miles above its mouth, having also a number of mills erected on it. The Muskingum rises near the sources of the Cuyahoga of Lake Erie, in the southern part of Connecticut Reserve. Its course is remarkably sinuous, but its general direction is to the southward. It has a long course, traversing a number of counties, is boatable in good stages of the water one hundred miles by the course of the river, and enters the Ohio at Marietta by a mouth two hundred and fifty yards wide. The Mahoning is also a large stream, which, with those already described, may be considered as belonging to the southern division of the state. In the north there is the Maumee, which rises in the north-eastern angle of the state of Indiana, and flows in a north-eastern direction, across the north-western borders of the state of Ohio, into the western extremity of Lake Erie. This important river has a course of one hundred miles, and is a broad, deep, navigable stream. It has a valuable fishery, and its banks in the season of vegetation are remarkable for the luxuriance of their verdure. The St Joseph, the St Mary's, and the Great and Little Au Glaize, are considerable tributary streams of the Maumee. The Sandusky rises in the western limits of Richland county, and runs in a general north-west direction ninety miles to the lake. It is more rapid than the other lake streams, but yet affords good navigation. Cuyahoga rises in the central parts of Geauga county, and falls into the lake at Cleveland, after a course of sixty miles, for the greater part of which distance it is boatable. Chagrin, Grand, Ashtabula, and Coneaught, are considerable streams, which rise near the lake, run in a northerly direction, and discharge their waters into it.

Ohio possesses an extensive and rich coal region in its eastern and north-eastern divisions, on the Muskingum, the Hockhocking, and the Scioto. The mineral is not only in great abundance, but of the best quality; and in the same region vast quantities of iron ore are found. Limestone, marble, and freestone abound; they are easily accessible, and are admirably adapted to building and public works. The useful earths and fossils are also in abundance. Specimens of gypsum are procured from Sandusky Bay. Salt springs are common, and some of them contain as much saline matter as the waters of the ocean. Nearly half a million bushels of salt are annually manufactured in the state. Those springs the waters of which are drank for medicinal purposes are most of them more or less impregnated with muriate of soda. The Yellow Springs, the most celebrated watering-place after Harrodsburgh Springs in the western country, are situated near the falls of the Miami, sixty-three miles from Cincinnati. The antiquities which belong to this state are somewhat similar to those described in the article New York; mounds of earth, in which have been found domestic utensils, pottery, vases, and trinkets.

Instruments of warfare have likewise been dug up, amongst which Mr Flint mentions a curious sword and an iron horse-shoe of a diminutive size.

Except along the deep vales of the Ohio, and those of the other streams near their influx into that great recipient, the climate is as uniform as the surface, and considerably more severe in the winter season than in corresponding latitudes on the Atlantic. But the other seasons are warmer, and the nature and luxuriance of the vegetation indicates a temperature of greater mildness in general. The summers are warm, and pretty regular, although to a certain extent subject to tornadoes. The central parts of the state are in the same latitude with Philadelphia. The mean temperature of the year at this city was found to be 53°; but during the same year that of Ohio was two degrees higher. As we recede from the Ohio, the temperature diminishes in a greater ratio than the latitude would indicate; but in general throughout the state there is a striking correspondence between the two. Whilst the summers are warm, the winters are very severe, and the river Ohio has occasionally been crossed at Cincinnati for nine consecutive weeks. At other times this season of the year is mild; but during the winter months the transitions from heat to cold and the reverse are frequent and violent. In that part of the state which slopes to the south, the snow seldom falls deep or lies long; but in Connecticut Reserve, and in the points which slope towards the lakes, they have deep and durable snows. Autumn is almost uniformly temperate, dry, and beautiful; and spring is also a pleasant season. The winds of Ohio, whether high or low, generally blow from the west and south-west at all times. In some parts, near marshes and stagnant waters, fevers and agues frequently prevail; but the climate in general is decidedly healthy.

Soil and productions.

The soil and the climate of Ohio together are admirably adapted to the most valuable vegetable productions which grow in such a latitude. The soil is very productive, without, however, being so remarkable in this respect as some parts of Illinois and Missouri. After the severity of winter abates, which is early in February, vegetation begins to put forth its powers; and as the heat of spring and summer takes effect upon the soil, it advances with astonishing rapidity. Ohio, generally, has a soil admirably adapted to wheat. Indian corn is the staple grain, and it is nowhere raised more easily, or in greater abundance. On rich alluvial soils 110 bushels have been produced from an acre; but fifty may be considered as about the average crop. Rye, barley, oats, spelts, buckwheat, and all other grains, are raised in great abundance and perfection. Melons, squashes, pumpkins, the pulses, garden vegetables both bulbous and others, as potatoes, onions, beets, carrots, parsnips, asparagus of the best description, and various culinary products of the soil, attain the highest development. From its stiff, clayey nature, the soil retains moisture well, and is better fitted for gardens than the soils farther west. Fruits of all kinds are raised in the greatest profusion; and apples in particular are very plentiful. Pears, plums, peaches, cherries, strawberries, grapes, and what not, are cultivated to such an extent as amply to supply the markets. "In a few years," says Mr Flint, "this state will take place of any in the Union, in the abundance and excellence of its fruits of all kinds. From the fulness and richness of the clusters of cultivated grapes, it is clear that this ought to be a country of vineyards. The Germans have already made a few establishments of the kind with entire success. Apricots, nectarines, and quinces succeed; and this state is the appropriate empire of Pomona. Recently, tobacco has been added to the articles cultivated. ...Hemp is an article of cultivation in some parts of the state. Agricultural improvement, however, proceeds with slow pace. The people generally are not at all given to experiment, and continue to farm in the old and beaten routine....Besides trees, shrubs, and vines, this state produces a great abundance of indigenous productions that are useful in medicine. We may mention *actea racemosa*, squaw root, Virginia snake root, Indian turnip, ginseng, which is dug in considerable quantities as an article of commerce, colombo, labelia, valerian, blood root or sanguinaria, canadensis, and various other herbaceous medicinal plants."

Commerce.

This state, being more populous than any other in the west, and possessing in many respects manufacturing capabilities, has taken precedence of all the rest in manufactures. Cotton yarn, cloth, and woollen goods, are already manufactured to a considerable extent, as are also flour and spirits; and family manufactures are likewise industriously prosecuted. The principal domestic articles of trade are horses, cattle, swine, whisky, flour, and tobacco. Those articles which are exported from the northern and some interior counties are frequently sent to Montreal and New York markets, by way of Lake Erie. From the southern parts of the state they are transported down the Ohio and Mississippi to New Orleans. Foreign goods are received from the same place by the steam-boats, and from Philadelphia and Baltimore across the Alleghany Mountains. "The surplus produce of the state of Ohio," says Mr Pitkin, in his Statistical View of the Commerce of the United States, "it is believed, may be calculated at about ten millions. The exports of Cincinnati alone, in 1833, were valued at five millions of dollars. This amount does not probably exceed the truth, when it is considered that the number of hogs slaughtered in that city in 1833 was 123,859, which would make as many, and probably more, barrels of pork, and, in the same year, 21,880 barrels of pork came to that city by the Miami Canal, making about 150,000 barrels in the whole, and which, at nine dollars per barrel, would be 1,359,000 dollars; and that in 1834, the number slaughtered was 150,000. And we cannot but here remark, that the whole quantity of pork exported from the United States in 1833 was only 105,870 barrels, leaving in favour of Cincinnati 45,000 barrels." It is of course taken for granted, that of the 150,000 barrels of pork said to be made at this city, all above the 45,000 entered as having been exported was reserved for home consumption. Mr Pitkin continues, "the exports of Cleveland on Lake Erie, in the same year, was 1,794,000 dollars coastwise, and 250,000 to foreign places, and from Huron 274,840 dollars; and from the country of Muskingum, on the river of that name, and from the flourishing village of Zanesville, with her numerous flourishing mills, as ascertained by those well acquainted with the facts, was 500,000 dollars. The value of the exports from these places alone make about seven millions and three quarters; and when it is considered that the quantity of tobacco raised in Ohio in 1833 was 10,000 hogsheads, only 3000 of which is included in the above exports from Muskingum, and when to these are added the exports from the Sciota valley, and from many other places on the Ohio River, and on the lake, we apprehend that the surplus produce of Ohio cannot be less than ten millions of dollars."

Statistics.

The following account of the statistics of Ohio for 1836 is taken from the American Almanac for 1837.

Value of Taxable Property.

	Dollars.
Lands (17,819,631 acres), including buildings	58,166,821
Town lots, including houses, mills, &c	15,762,594
Horses (262,291, valued at forty dollars each)	10,491,640
Cattle (455,487, valued at eight dollars each)	4,043,896
Merchants' capital and money at interest	7,262,927
Pleasure-carriages, 2603, valued at	199,518
Total	95,927,396

Ohio.

Taxes Levied.

	Dollars.
State and canal tax	142,854·15
County and school tax	396,505·80
Road tax	66,482·16
Township tax	102,991·65
Corporation, jail, and bridge tax	51,276·89
Physicians' and lawyers' tax	3,144·19
School-house tax	1,482·84
Delinquencies of former years	13,044·37
Total	777,782·05

Foreign debt, 4,400,000 dollars;—legal interest	260,000
Domestic do.....579,287 dollars;—ditto	34,757
Total...4,979,287	294,757
Canal tolls for 1835, and receipts from the sale of Ohio canal lands	306,906
Amount of school funds on loan to the state, 15th November 1835	803,432

Although the first permanent settlement was made in Ohio not more than fifty years ago, and although it was admitted into the Union as a state as recently as 1802, yet it has now become one of the most considerable states in the union, has entered largely into the system of internal improvement, and has constructed one of the longest canals in the world. The state canals are under the direction of a board of canal commissioners; and the Ohio and Miami Canals, which, together with their branches, are more than four hundred miles in extent, have been constructed at the expense of the state. For an account of the canals of Ohio, see the article NAVIGATION, INLAND.

Railroads. Railroads have likewise been constructed on the same extensive scale, and numbers of them are in course of being laid. Mad River and Lake Erie Railroad, extending from Dayton to the city of Sandusky, is to be 153 miles in length. The Pennsylvania and Ohio Railroad is designed to commence at Pittsburgh, and terminate at Massillon on the Ohio Canal, the length being 180 miles. There are some others of smaller size; and some idea may be formed of the extent to which these works are carried, from the fact that no less than twenty-eight companies were incorporated in the year 1836. In connection with trade and internal improvement may be mentioned the banks of Ohio. In the year 1835 there were thirty-one banks in this state; and the condition of twenty-nine of these, from which returns were received, was, that they had of specie 1,906,715, and of capital 6,390,741; and that their circulation was 5,654,048. The legal interest in Ohio is six per cent.; but there is no law against usury, so that in some parts it is seldom less, and often more, than ten per cent.

Education and literature. A laudable zeal has been shown to diffuse education throughout this state. In the year 1825 the New England system of tuition was introduced into Ohio, and by various emendatory enactments it has now acquired a degree of form and consistency. By an act of the state the trustees of every incorporated township are required to divide it into a suitable number of school districts, the prudential concerns of which are managed by three school directors, a clerk, and a treasurer. The funds for maintaining this vast system arise from various sources besides the easy tax of one mill upon a dollar, constituting a large and growing revenue. By this act it is provided that the youth of every class, without distinction, shall be instructed in reading, writing, and arithmetic, as well as in other necessary branches of education. There are no less than nine colleges or universities, viz. the university of Ohio, at Athens, with five instructors, seventy-two alumni, twenty-six ministers, forty-five students, and about a thousand volumes in the college library, and as many in that of the students; the Miami university, at Oxford, with eight instructors, eighty alumni, seventeen ministers, one hundred and twenty-six students, and 1200 and 2500 volumes respectively in the college and students' libraries; the Franklin university, at New Athens; the Western Reserve university, at Hudson; the Kenyon university, at Gambier; the Granville university, at Granville; the Marietta university, at Marietta; the Oberlin institution, at New Illyria; and the Willoughby university, at Chagrin; all of which are smaller than the first two, but have from fifty to one hundred students. There are five theological seminaries, a presbyterian college at Cincinnati, and another at Hudson, a Protestant episcopal college at Gambier, a Lutheran theological school at Columbus, and a Baptist institution of the same kind at Granville. There are two medical schools; one at Cincinnati, having six professors, and another at Northing, with four professors. There is a law college at Cincinnati, which has three professors. Amongst institutions of a public character may be mentioned an asylum for the deaf and dumb, which has been established at Columbus. Literature is making considerable progress in Ohio. In 1810 there were only fourteen newspapers in the state, and in 1834 their number amounted to 140. There are, besides, several other periodicals of a literary and scientific nature.

Religion. Almost every religious denomination is found in this state, but the Presbyterians and Methodists predominate. In 1831, which is the latest complete return that we have obtained, the numbers were, of Presbyterians, 22,150 communicants, having 346 churches; of Baptists, 8801 communicants, having 240 churches; of Methodists, 36,064 members; of Lutherans, 8706 communicants; of Associate Presbyterians, sixty-five congregations; of German Reformed, eighty-two congregations. The Episcopalians had also sixteen ministers, and the New Jerusalem church four societies; and there were, besides, a number of Friends and Roman Catholics, and some Universalists, Unitarians, and Shakers. "It is affirmed by a gentleman," says Mr Flint, "well known for his researches into the antiquities of this state, that there is a greater number of professors of religion, in proportion to the whole number of the people, than in any state in the Union. There are a vast number of religious societies; but there is not a great number that have regularly established pastors. The custom of itinerating preaching, as a supply, is very prevalent. The people are generally a quiet, orderly, peaceable, moral, and industrious race. Suicide, excesses, murders in affray, and instances of deliberate and atrocious cruelty, are rare; and the general moral character of the people is highly respectable."

From the census of 1830 we learn that there were at that time in Ohio the remains of Indian tribes, amounting to 2350 persons. They then owned 390,846 acres of land, besides 16,200 acres which were secured to individuals belonging to the several tribes. These lands are secured by treaty to the Wyandotes, Shawnees, Senecas, Delawares, and Ottawas; the other remnants of tribes being classed with these. Some of them have sold their shares; but to those which still hold them, considerable annuities are paid by the national government. The number of individuals belonging to these tribes is gradually diminishing, and they must soon entirely disappear in the tide of white population which is fast overspreading their native territories. There are not many negroes in Ohio, and none are held as slaves. Few descriptions of the inhabitants are exempted from military duty. The militia of this state is principally composed of hardy agriculturists, and exceeds one hundred and fifty thousand men. A portion of the land in Ohio still belongs to the United States. In the north-east part of the state there is a tract containing 3,300,000 acres, called New Connecticut, or Connec-

Ohio. ticut Western Reserve. The fee of these lands is in the state of Connecticut, but Ohi has the jurisdiction. The state of Virginia also owns a tract of above four millions of acres, called the Virginia military lands, which are situated between the Scioto and Little Miami Rivers. The following table exhibits the

Population of the Counties and County Towns of the State of Ohio in 1830.

Counties.	Population in 1830.	Square Miles.	County Towns.	Population.	Distance from Cincinnati.	Distance from Washington.

The increase of population in the state of Ohio has been rapid almost beyond example. In the year 1790 it was only about 3000; in 1800, 45,365; in 1810, 230,760; in 1820, 581,434; and in 1830, 937,679.

For an account of Cincinnati, the principal city of Ohio, see the article Cincinnati. Columbus, the political metropolis, is situated near the centre of the state, upon the east bank of the Scioto River. The beautiful slope on which it stands, just below the confluence of the Whetstone River with the Scioto, was a compact forest in 1812. It is now cleared and well cultivated, and the city contains some excellent public buildings, including a penitentiary, an asylum for the deaf and dumb, and above three thousand inhabitants. Steubenville, the seat of justice for Jefferson county, is situated on the western bank of the Ohio, near the Pennsylvania boundary. It was laid out with great regularity in 1798, and is situated in the centre of a rich and populous country. It has the usual number of public buildings found in towns of the same size, and it possesses cotton, woollen, and other manufactures. Chillicothe is finely situated upon a level alluvial plain on the west bank of the Scioto, forty-five miles in a right line from its entrance into the Ohio. It was laid out with great regularity in 1796, and contains some handsome buildings. It possesses several cotton factories, and a number of flour and other mills. Marietta, the oldest town in the state, is situated on the Ohio, a little above the mouth of the Muskingum River. Ships were formerly built here, but this business has been discontinued, and the town, although very advantageously placed, has not prospered like many others in the state less favourably situated. Sixty miles north of Marietta, on the Muskingum, is the town of Zanesville, principally distinguished for its manufactures of iron. Here there are likewise a number of flour and other mills, driven by the waters of the Muskingum; and two or three glass-houses. Cleveland, situated upon the southern shore of Lake Erie, at the mouth of Cuyahoga River, is destined, from its position, to become an important town. It is one of the principal points for embarkation on the lake, and during the last American war was a provision dépôt, and a place where many boats and other lake craft were built. Cleveland is intermediate between Buffalo and Cincinnati, and is the dépôt of that vast quantity of merchandise which is destined for the east and west. One of the most important places on Lake Erie is Sandusky, situated on the southern shore of a bay of the same name. Although it is comparatively a young settlement, it has a great number of stores, and is one of the chief points of landing and embarkation between the Mississippi Valley and New York, Buffalo, and Detroit. The other ports or harbours on Lake Erie are Put-in Bay, Maumee Bay, Fair Port, and Ashtabula Creek. The relative importance of these, as well as the other towns belonging to Ohio, will be seen from our tabular view of the counties and county towns.

The first permanent settlement in the state of Ohio was made at Marietta, on the 7th of April 1788, by forty-seven persons from Massachusetts, Rhode Island, and Connecticut. In the year following a settlement was made at Columbia, six miles above Cincinnati, by a company principally from Pennsylvania. In September 1799, the first territorial legislature assembled at Cincinnati, under the ordinance of congress of the 13th July 1786, for the government of the territory of the United States north-west of the river Ohio. On the 30th of April 1802, congress passed an act authorizing the calling of a convention to form a state constitution for that part of the North-west Territory which now constitutes the state of Ohio. On the 1st of November following the convention met at Chillicothe, and formed the present constitution, by which Ohio was admitted into the union. The following is an outline of the constitution of Ohio. The legislative power is vested in a senate and house of representatives, which together are styled the General Assembly of the State of Ohio. The representatives are elected annually on the second Tuesday in October; and they are apportioned amongst the counties according to the number of white male inhabitants above twenty-one years of age. Their numbers cannot be less than thirty-six, nor more than seventy-two. The senators are chosen biennially, and are apportioned according to the number of white male inhabitants of twenty-one years of age. Their number cannot be less than one third, nor more than one half of the number of representatives. The executive power is vested in a governor, who is elected by the people for two years, on the second Tuesday in October; and his term of service commences on the first Monday in December. The general assembly meets annually at Columbus, on the first Monday in December. The right of suffrage is granted to all white male inhabitants above the age of twenty-one years, who have resided in the state one year next preceding the election, and who have paid or are charged with a state or county tax. The judicial power is vested in a supreme court, in courts of common pleas for each county, and such other courts as the legislature may from time to time establish.

The judges are elected by a joint ballot of both houses of the general assembly, for the term of seven years. (R. R. R.)

OHIO, a great river of the valley of the Mississippi, in North America, formed by the confluence of the Alleghany and Monongahela Rivers at Pittsburgh, in the western part of Pennsylvania. The highest sources of the Alleghany are in Potter county, Pennsylvania, twelve miles to the eastward of Condersport, where they interlock with the head waters of the Genessee River, and the eastern and western branches of the Susquehannah. During its course through Pennsylvania, which is exceedingly irregular, it is joined by several streams, the most considerable of which are, Toby's Creek, extending one hundred miles into the interior of Pennsylvania, and the Kiskiminitas, formed by the junction of the Conemaugh and Loyalhanna, which rise near the Alleghany Mountains, one hundred miles distant. This branch of the Ohio, although its volume is not apparently wider than the other, is by far the most important tributary. It has a swift, sweeping, and rapid current, and often a rocky bottom, whence huge blocks rise to the surface of the water. In the spring time, when it is full, flat and keel boats descend it rapidly, without any danger. It has been navigated by steam-boats, but has been found one of the most difficult currents to stem ever attempted by these vessels. Monongahela River, the other fork of the Ohio, rises in Virginia, about seventy miles north-west of Morgantown. It traverses a rich and well-settled country, celebrated for its whisky, flour, and iron manufactures. The banks are often bold and high bluffs, and in some places the country is hilly. In good stages of the water, it is boatable by large boats for about one hundred miles from its mouth. During its course it receives the waters of a number of tributary streams, the most important of which is the Youghiogeny River, or, as it is commonly called, the Yough, which rises near the upper waters of the Potomac, the rivers being only separated by a spur of the mountains. From the western declivity of these mountains, both this and the main river receive a great accession of mountain streams. The united current, which has now become broad and majestic, flows in a north-west course to Pittsburgh, and where it unites with the Alleghany it is more than four hundred yards in breadth. At the confluence of the two great branches, the Ohio is somewhat more than six hundred yards wide, and it immediately assumes that broad, placid, and beautiful aspect which it maintains to its junction with the Mississippi, in latitude 37. 0. north, and longitude 88. 52. west. Its length from Pittsburgh to its mouth is about nine hundred miles, including the windings of the river; but the direct distance is only six hundred and fourteen miles. Its breadth varies exceedingly, being in some parts fourteen hundred yards, whilst in others it is only four hundred yards across. At Cincinnati it is about eight hundred yards wide, and this is nearly its average breadth. For thirty miles below Pittsburgh its course is north-west. It then turns slowly to the west-south-west, and pursues that general direction for some five hundred miles. It flows south-west for above one hundred and fifty miles, then westward above two hundred and fifty miles, and finally south-west about one hundred and seventy miles through that low and swampy country in which it joins the "Father of waters." Between Pittsburgh and its mouth it is diversified with about one hundred considerable islands, besides a great number of tow-heads and sand-bars, which in low stages of the water greatly impede navigation. Some of these islands are of exquisite beauty, and afford most lovely situations for retired farms. The passages between them and the sand-bars at their head are amongst the difficulties of the navigation of the river. Notwithstanding these obstacles, however, it is well adapted for boat navigation, the current being remarkably smooth and gentle, excepting at Louisville in Kentucky, where it is broken by falls, the water running for several miles with great rapidity, although not so much so as to be insurmountable by boats. A canal round these falls, a work of great magnitude and utility, has been completed. The annual range of the Ohio, from low to high water, is about fifty feet; the extreme range is ten feet more. When lowest it may be forded at several places above Louisville. It is generally lowest in August, September, and October, and highest in December, March, May, and June. Throughout the year it is subject to sudden and very considerable elevations and depressions. Near Pittsburgh it is frequently frozen over for several weeks during the winter, and this has sometimes been the case four hundred miles lower down. Generally, the navigation upward is suspended by floating ice for eight or ten weeks in winter. When the river is at its mean height, its current is about three miles an hour; when higher and rising it is more, and when very low it does not exceed two miles an hour. Above two hundred steam-boats ply on the Ohio, a great part of which are employed in the commerce of the states bordering on the river; but they also connect with it the commerce of the states on the Mississippi. The produce of the contiguous states is readily transported to this channel by the numerous navigable rivers which it receives, and is thence conveyed to New Orleans, the grand commercial emporium of the valley of the Mississippi. The Ohio and all its tributaries cannot, it is believed, have less than five thousand miles of boatable waters; and, taking all circumstances into account, few rivers in the world can vie with it, either in utility or beauty. From its very commencement it affords most delightful prospects. Rivers of a romantic and beautiful character flow into it almost at equal distances, like lateral canals. Its valleys are of extraordinary depth and fertility; generally high and dry, and for the most part healthy; whilst the configuration of the country on the banks has much grandeur, softness, and variety. Of the rivers and creeks which join the Ohio, the number is very great. The following are all navigable, in moderate or high stages of the water, by steam-boats, for considerable distances, viz. the Muskingum, Great Kenhawa, Big Sandy, Scioto, Great Miami, Kentucky, Green, Wabash, Cumberland, and Tennessee. The last is by far the largest and most important tributary of the Ohio, watering considerable portions of Alabama, Tennessee, and Kentucky. Of creeks and smaller rivers there are probably nearly two hundred which enter the Ohio; but a list of them would only be a dry catalogue of uncouth names. (R. R. R.)

OHITTAHOO, one of the Marquis of Mendoza's Islands, in the Southern Pacific Ocean. It is about nine miles in length and twenty-one in circumference, and is intersected by a narrow ridge of hills, which are divided by deep, narrow, and fertile valleys, well watered, and adorned with trees. This, with other three islands which lie near it, was discovered in July 1595, by Alvaro Mendana, who gave them their name, in honour of the viceroy of Peru. A cove in which the European vessels usually anchored is situated in long. 139. 8. W. and lat. 9. 55. S.

OHRDRUFF, a city of the duchy of Saxe-Gotha-Altenburg, in Germany, the capital of a bailiwick of the same name, which, besides the city, contains six villages, 1700 houses, and 7000 inhabitants. It belongs to Prince Hohenlohe-Neuenstein. The city stands near the borders of the Thuringian Mountains, on the small river Ohre. It is surrounded with walls, and has a palace for the prince, four churches, a lyceum, an hospital, 840 dwellings, and 3480 inhabitants, who are industrious in making wood ware, in tanning leather, and in producing paper, copper utensils, and several smaller articles.

OIA, a river of Asiatic Russia, which falls into the Gulf of Obskaia. Long. 72. 24. E. Lat. 68. N.

OIL, an unctuous and inflammable substance, obtained from several natural bodies, as animal and vegetable substances.

OISE, a department of the north of France, formed out of the ancient Isle of France, and the districts of Beauvaisis and Valois. It extends in north latitude from 49. 7. to 49. 38. and in east longitude from 1. 28. to 3. 4. It is bounded on the north by the Somme, on the east by the Aisne, on the south by the Seine and Marne and the Seine and Oise, and on the west by the Eure; and it is divided into four arrondissements, which are subdivided into thirty-five cantons and 738 communes. It extends over 2428 square miles, and, according to the census of 1836, contains 398,641 inhabitants, and elects three deputies to the national representative body. The face of the country is plain or undulating, with a chain of calcareous hills of moderate height, of which Mount Cæsar on the eastern part is the highest. The soil is various, being in some parts clayey and in others sandy with marl, and generally a calcareous subsoil, except in the marshy portions near the streams. The Oise runs through it till it falls into the Seine, and it is navigable for barges. The Aisne, another navigable river, passes through a part of this department before it joins the Oise. There are a great number of smaller streams, some with and some without a name, all of which reach the sea ultimately through the Seine. The climate is dry and healthy, except in the marshy parts and near the woods, which cover about one seventh part of the whole surface. The agriculture is tolerably conducted; but the paucity of manure causes a great part of the land to be left fallow; yet it yields more corn than is required for the consumption, and in average years can spare one fourth of its growth for the supply of the surrounding departments. Besides corn, it yields a vast quantity of fruit, especially cherries, which can be conveyed by the rivers to Paris and other large cities. A great quantity of apples is converted into cider. The vines in general produce only a weak wine, not capable of being long preserved, except some of Ancerville and of Villars-Saint-Sepulcre, which are preferred to all the others of Picardy. The breeding of horses is carefully attended to, and some excellent ones are reared. The stock of oxen and sheep is low for the extent of country; but the races of the latter have been recently improved by the crossings with Merinos, and some fine wool is now furnished to the manufacturers. There are fabrics of linen, woollen, and cotton goods in several places; a considerable quantity of thread lace is made by the females; and there are also many tanneries and potteries. There is a considerable transit trade on the rivers, and they, as well as the rivulets, afford much fish.

OKEHAM, or OKHAM, a market-town, the capital of the county of Rutland, and situated in a rich valley called the vale of Cadmus. It is ninety-five miles from London, and has a good market on Saturday. It has an ancient castle, now converted into an assize-hall and a county jail. The parish church, dedicated to All-Saints, is a fine old structure, with a lofty spire, which is visible a great way around it. It has no corporation; but whatever power of a municipal nature is exercised is derived from the Earl of Winchelsea or the Dean of Westminster, who are lords of the two manors into which the town is divided. Near to it is Burleigh-on-the-Hill, a noble mansion of the Earl of Winchelsea. The population amounted in 1801 to 1613, in 1811 to 1719, in 1821 to 2160, and in 1831 to 2440.

OKHOTZK, one of the four circles of Asiatic Russia, in the government of Irkoutsk. It extends along the gulfs of the Eastern Ocean, called the Seas of Okhotzk, of Kamtschatka, and of Anadir. The climate is damp and unhealthy, being exposed to thick mists, from so great an extent of ocean; and the country is not only barren, but unwholesome. This damp and poisonous atmosphere continues for ten miles inland, when the sea air is arrested by a ridge of moderately-elevated hills. Beyond this boundary the country is more fertile, as trees are found to grow well, and rich meadows are seen.

The town of Okhotzk is built upon a long and narrow ridge, enclosed between the sea and the river Okhota, and formed chiefly from an accumulation of marine débris. This town consists of 130 houses, extending in a line of about two thirds of a mile, though it is not more than from 100 to 300 feet broad. It has a church, some magazines, and a double row of shops. Okhotzk is the channel of trade between Irkoutsk and Kamtschatka. The goods are conveyed chiefly by water, there being a very short interval of land carriage. But it is a tedious and difficult voyage, and even dangerous from the barbarous nature of the people who inhabit the banks of the rivers. The land journey is likewise dangerous. So difficult is the country, that the goods can be carried only on pack-horses, or on men's backs, as there are no waggons of any description; and, on account of the danger of sinking in morasses, it can be performed only in the spring. The inhabitants of the town consist chiefly of mariners and Cossacks. Besides the officers of the court of justice, there are two priests. Long. of the town 142. 44. E. Lat. 59. 20. N. The Sea of Okhotzk is a large gulf of the Eastern Ocean, enclosed between Kamtschatka, the circle of Okhotzk, part of Chinese Tartary, and Saghalien. At its mouth are the Kurile Islands and part of Jesso.

OKIRAH, a town of Bengal, in the district of Burdwan, 105 miles north-west from Calcutta. Long. 87. 15. E. Lat. 23. 38. N.

OLANGO, a small island amongst the Philippines, near the eastern coast of Siba. Long. 123. 51. E. Lat. 10. 33. N.

OLCHANSKAIA, a fortress of Asiatic Russia, in the government of Orenburg, and situated on the small river Olchanka. It contains a church and several streets, and forms part of the military line of Samara. The inhabitants consist chiefly of veteran soldiers. It is 177 miles south-east of Orenburg.

OLDCASTLE, SIR JOHN, commonly called the Good Lord Cobham, was born in the reign of Edward III. He obtained his peerage by marrying the heiress of that Lord Cobham who had strenuously opposed the tyranny of Richard II.; and, with the estate and title of his father-in-law, he seems to have acquired the patriotic and independent spirit for which that nobleman was distinguished. By his means, the statute against provisors was revived, and guarded with more severe penalties than ever; and he was also one of the leaders of the party who, having drawn up a number of articles against the corruptions which then prevailed amongst ecclesiastics, presented them in the form of a remonstrance to the Commons. He was at great pains in collecting and transcribing the works of Wickliffe, which he dispersed amongst the people; and he sent a number of his disciples as itinerant preachers into various parts of the country. In the reign of Henry IV. he commanded an English army in France, at that time distracted by the contentions of the two factions of Orleans and Burgundy; and, in this capacity, he compelled the Duke of Orleans to raise the siege of Paris. In the reign of Henry V. he was accused of heresy, the growth and extension of which was mainly attributed to his influence. The king having a favour for Lord Cobham, who held a domestic office at court, delayed the prosecution, and kindly undertook, by reasoning and expostulation, to reclaim him from his errors. But the attempt proved abortive. "Next to God," said his lordship, "I profess obedience to my king; but as to the spiritual dominion of the pope, I could never see upon what foundation it is claimed, nor can I pay him any obedience;" and he added, "It is as sure as God's word is true, he is the great Antichrist foretold in holy writ." This answer, so different from what had been expected, deeply offended the king, who, turning away in visible displeasure, withdrew his favour from Cobham, and left him to the censures of the church, which speedily overtook him. Being summoned to appear before the archbishop, he disobeyed the citation, and was excommunicated on the ground of contumacy. Reckless in exposing himself to danger, he seems to have wanted the courage to confront it boldly when it appeared in a definite shape. Hoping to avoid the impending storm, he waited upon the king with a confession of his faith in writing; but whilst he was in the royal presence, an officer of the ecclesiastical court entered, and cited him to appear before the archbishop, upon which he was immediately conveyed a prisoner to the Tower. When brought before the proper tribunal, he read his opinion of the several articles in regard to which he supposed that he had been called in question, particularly the eucharist, images, penance, and pilgrimages; but he was informed, that in some things he had not been sufficiently explicit in stating his particular views; that on all these points the church had already decided, and by her determinations all Christians ought to abide; that these determinations would be given him as a direction of his faith; and that, in a few days, he must appear again and state his opinions. The second examination, however, ended like the first. Cobham declared that "he knew none holier than Christ and his apostles; and that these determinations were surely none of theirs, as they were against Scripture." He was accordingly condemned as a heretic, and remanded to the Tower; but he contrived to effect his escape from prison, and lay concealed in Wales, until information reached the king at Eltham that about twenty thousand Lollards had assembled for his destruction at St Giles, with Lord Cobham at their head. A bill of attainder then passed against him, a price was set upon his head, and a perpetual exemption from taxes promised to any town which should secure him. After having spent four years in Wales, he was at length seized, carried to London, and executed in St Giles's Fields, in December 1417, with circumstances of cruelty characteristic of the times.

As a writer, Lord Cobham is only known by a piece entitled "Twelve Conclusions, addressed to the Parliament of England," at the end of the first book of which are some monkish rhymes in Latin, which Bale has preserved. "A Brefe Chronycle concerning the Examynacyon and Death of the blessed martyr of Christ, Syr Johan Oldecastell, the Lorde Cobham," was also published by Bale, and reprinted under the care of a Mr Lewis of Margate in 1729. Since that time the life of Lord Cobham has been written by Mr Gilpin, who describes him as a person of uncommon parts and varied talents, well qualified either for the cabinet or the field; as possessing acquirements equal to his parts; and, besides, as remarkable for his ready and poignant wit in conversation. "It was his thirst of knowledge," adds his biographer, "which first brought him acquainted with the opinions of Wickliffe. The novelty of them engaged his curiosity. He examined them as a philosopher, and in the course of his examination became a Christian." (A.)

OLDENBURG, a sovereign duchy in the north-east of Germany, but consisting also of two other portions separated from it, though both of them are of small extent. One of these smaller divisions in the north is called the principality of Lubeck, consisting of a small territory surrounded by the Danish territory of Holstein, and some small spots on the banks of the Trave, and near Schwartau, adjoining to the territory of the republic of Lubeck. The other of these small divisions is on the western side of the Rhine; it is called the principality of Birkenfeld, and is wholly surrounded by the Prussian province of the Lower Rhine. The whole of these three divisions extend over 2721 square miles, and comprehend nine cities, ten market-towns, and 776 villages and hamlets, with 233,400 inhabitants, of whom 161,420 adhere to the Lutheran church, 68,000 are Catholics, and the remainder, excepting 900 Jews, are Calvinists. The population of the principality of Lubeck is 19,070, that of Birkenfeld is 21,180, and the remainder is found in Oldenburg proper. The revenues of the state amount to about L.130,000 annually, arising partly from tolls on the Weser, and partly from taxes on foreign goods, but chiefly from domains. The state has no debt. The army consists of 1650 men; but the state is bound to contribute to the force of the German confederacy a contingent of 2177 men. The principal river is the Weser, into which the smaller streams flow, and it is the ordinary channel of marine commerce. The soil is in general poor and sandy, but near to the rivers there are some rich marshes, obtained by draining and embankments, which fatten cattle, and afford the productions of the dairy. The cultivation is badly conducted in the large division. There are a great number of small proprietors, who cultivate their own fields, and thereby procure a bare subsistence. The climate is raw, cold, and exceedingly variable.

OLDENBURG, a city, the capital of the duchy of the same name in the north-east of Germany. It is situated on the river Hunte, which is navigable to the Weser, and is surrounded with walls planted with lime trees, being well built and clean, but in an antique style. The duke has a large and old, but not an elegant palace, on the grand parade, adjoining to the city. The city contains two churches, two hospitals, and 660 houses, with 5420 inhabitants, who subsist chiefly from the expenditure of the court, of the tribunals, and of the civil officers of the government. It has little trade excepting at its two great fairs. Long. 8. 6. 1. E. Lat. 53. 8. 33. N.

OLDENBURG, *Henry*, was born in the duchy of Bremen, in Lower Saxony. During the long parliament, he was appointed consul for his countrymen, at London, after the usurpation of Cromwell; but being discharged of that employment, he was appointed tutor to the Lord Henry O'Bryan, an Irish nobleman, whom he attended to the university of Oxford, where he was admitted to study in the Bodleian Library in the beginning of the year 1656. He was afterwards tutor to William Lord Cavendish, and was acquainted with Milton the poet. During his residence at Oxford he became acquainted with the members of that body, which there gave birth to the Royal Society, upon the foundation of which he was elected a fellow; and when the society had found it necessary to have two secretaries, he was chosen as assistant secretary to Dr Wilkins. He applied himself with extraordinary diligence to the business of his office, and in the year 1664 began the publication of the *Philosophical Transactions*, which he continued to publish to No. xxxvi. 25th June 1677. After this the publication was discontinued till the January following, when it was again resumed by his successor in the office of secretary, Mr Nehemiah Grew, who carried it on till the end of February 1678. Mr Oldenburg died at his house at Charlcton, near Greenwich, in Kent, in August 1678.

OLDHAM, one of those towns which, within the present generation, have grown up with rapidity since the establishment of the cotton manufacture. It is situated in the hundred of Salford, in the county of Lancaster, eight miles from Manchester, and 186 from London. It stands on the river Medlock, very near the source of that and of another stream called the Irk, in a district abounding in coal. Oldham had been created into a market-town; and was by the reform act constituted a borough, with the power of returning two members to the House of Commons. It is parochially united with Prestwick, and these places comprehend ten townships, extending over 21,160 acres, with a population, in 1831, of 67,579 persons. The whole is a manufacturing district, making fustians and spinning cotton yarn, and also having a great trade in making hats. The town of Oldham is, for the most part, of very recent erection, containing many large piles of buildings destined for manufacturing purposes, and a proportional number of small dwellings for the workmen; but all are discoloured by the smoke which issues from numerous steam-engines, few of the proprietors of which reside within the town. It has a fine large parish church, and, as is usual with such a population, a very great variety of places of worship for the several discordant and dissenting sects. At the first election for this borough, it was distinguished by its selection of Mr Cobbett as one of its representatives. The population of the township of Oldham amounted in the year 1801 to 12,024, in 1811 to 16,690, in 1821 to 21,662, and in 1831 to 32,381.

OLDHAM, *John*, an eminent English poet of the seventeenth century, was educated under his father, a nonconformist minister, and then sent to Edmund Hall in Oxford. He afterwards became usher to the free school at Croydon in Surrey, where he received a visit from the Earls of Rochester and Dorset, Sir Charles Sedley, and other persons of distinction, merely on account of some verses of his which they had seen in manuscript. He was successively tutor to the sons of several gentlemen; and having saved a small sum of money, he came to London, where, being an agreeable companion, he became a perfect votary to the bottle. He was quickly found out by the noblemen who had visited him at Croydon, and who made him acquainted with Dryden. He lived mostly with the Earl of Kingston, at Holme Pierr-point, in Nottinghamshire, where he died of the small-pox in 1683, in the thirtieth year of his age. His acquaintance with learned authors appears, by his satires against the Jesuits, to have been considerable; and Dryden esteemed him highly. His works, which are printed in two vols. 12mo, consist chiefly of satires, odes, translations, paraphrases of Horace and other authors, elegiac verses, imitations, parodies, and familiar epistles.

OLDMIXON, JOHN, a violent party-writer and ill-natured critic, who would scarcely have been remembered, if Pope, in resentment of his abuse, had not condemned him to immortality in the Dunciad. His party-writings procured him a place in the revenue at Liverpool, where he died at an advanced age, in the year 1745. Besides his fugitive pieces, he wrote a History of the Stuarts, in folio; a Critical History of England, in two vols. 8vo; a volume of Poems; and some dramatic pieces.

OLEKMA, a river of Asiatic Russia, in the government of Irkoutsk, and a tributary of the Lena. Its course is from south to north, and is in length nearly 600 miles. The animal which produced the sable fur formerly haunted its banks, but it has now disappeared.

OLEKMINSK, a fort and small town of Asiatic Russia, in the government of Irkoutsk. It was originally erected as a station for collecting the tribute of furs from the Yakoutes, who wander in the neighbouring districts. It has some twenty houses and a church, and is situated about nine miles from the mouth of the Olekma. It is 692 miles north-east of Irkoutsk.

OLENEK, a considerable river of the government of Irkoutsk, in Asiatic Russia, which discharges itself into the Frozen Ocean. Long. 119. E. Lat. 73. N. The small town of Olensk is situated near the mouth of the Olenek.

OLENUS, a Greek poet, older than Orpheus, who was a native of Xanthe, a city of Lycia. He composed several hymns, which were sung in the island of Delos upon festival days. Olenus is said to have been one of the founders of the oracle at Delphi; to have been the first who at that place filled the office of priest of Apollo; and to have given responses in verse.

OLERON, an arrondissement of the department of the Lower Pyrenees, in France, being 972 square miles in extent. It comprehends eight cantons, which are divided into eighty-one communes, and it contains 71,400 inhabitants. The capital is the city of the same name, situated between the two rivers Gaves d'Aspe and Gaves d'Ossau. It contains 900 houses, and6400 inhabitants, who are employed in making thin woollen hosiery and leather. Long. 0. 17. W. Lat. 43. 10. N.

OLERON, an island situated on the coast of France, in the department of the Lower Charente. It is about ninety square miles in extent, and is opposite the mouths of the rivers Charente and Seudre. It is separated from the mainland by the strait called the Pertuis de Maubuisson. Oleron is a fertile spot, especially on the east and south parts, and yields good corn, wine, and brandy. There are also extensive marshes, from which salt is collected. It contains about 15,000 inhabitants, who are expert seamen and fishermen.

OLIGARCHY, a form of government in which the administration of affairs is confined to a few hands.

OLIO, or OGLIO, a savoury dish, or food, composed of a great variety of ingredients.

OLIVAREZ, DON GASPAR DE GUZMAN CONDE DE, the favourite and minister of Philip IV. of Spain, a man of great parts and boundless ambition. After a restless and unprincipled career, he was banished to Toro, where he died about the year 1645.

OLIVE'S ISLAND, a small island lying off the south coast of New Holland, and belonging to the Nuyts Archipelago. Long. 133. 53. E. Lat. 32. 46. S.

OLIVET, or MOUNT OF OLIVES, was situated to the east of the city of Jerusalem, and separated from the city only by the brook Kedron, and by the valley of Jehoshaphat, which stretches out from the north to the south.

OLIVETAN, ROBERT, a son of John Calvin. He printed, at Neufchatel, in 1535, folio, a version of the Bible into French, which had been translated from the original Hebrew and Greek. It is written in an uncouth and barbarous style, and is very far from being faithful. The characters in which it is printed are Gothic, and the language is scarcely less so. It is valued only because it is rare. Calvin is believed to have had a considerable share in this translation. Olivetan survived his publication only a short time. He died at Rome the year after, having, it is alleged, been poisoned on account of his translation. Olivetan's Bible, revised by Calvin and Malinger, was reprinted at Geneva, in 1540, in 4to. This edition is still rarer than the former. It is called the *Bible de l'Epée*, because the printer had adopted the figure of a sword as his ensign.

OLIVIER, CLAUDE MATTHIEU, advocate of the parliament of Aix, was born at Marseilles, in 1701. He had a principal share in the establishment of the academy of Marseilles, and was one of its original members. He practised at the bar with considerable success; and a few hours' retirement from society and from his pleasures were frequently sufficient to enable him to speak and write, even upon important causes. But his works commonly bore marks of great haste. Addicted to excess in every thing, he would employ a fortnight in studying the Code and the Digest, or in storing his mind with the beauties of Demosthenes, Homer, Cicero, and Bossuet; and would then abandon himself for another fortnight, frequently for a whole month, to a life of frivolity and dissipation. He died in 1736, at the age of thirty-five. Olivier published, 1. L'Histoire de Philippe Roi de Macedoine, et Père d'Alexandre le Grand, 2 vols. 12mo; 2. Mémoire sur les Secours donnés aux Romains par les Marseillois pendant la Seconde Guerre Punique; 3. Mémoire sur les Secours donnés aux Romains par les Marseillois durant la Guerre contre les Gaulois.

OLLERTON, a small market-town of the county of Nottingham, in the hundred of Bassetlaw, a part of the parish of Edwinston, of which it is a chapelry. It is 133 miles from London, and thirteen from Nottingham, and has a market, which is held on Friday. The population amounted in 1801 to 439, in 1811 to 462, in 1821 to 576, and in 1831 to 658.

OLMUTZ, a city of the Austrian province of Moravia, the capital of a circle of the same name, which extends over 2090 square miles, and comprehends twenty-seven cities, twenty market-towns, and 795 villages, with 410,000 inhabitants. It is for the most part a mountainous country, and the principal rivers of the province have their sources in it. The southern part is the least hilly, and is a very fertile and well-cultivated district. The city, which stands on the river March, is fortified, and defended by a citadel, in which Lafayette was long a prisoner. It is a well-built place, being the see of an archbishop, and the seat of the administration of the province; and it has a lyceum, with a good library, twenty-six professors, and about 800 students, who are admitted to graduate in the four faculties of law, philosophy, medicine, and theology. It contains 680 houses, and, besides the military, about 12,000 inhabitants. It has little trade, and none but small manufactories. Long. 14. 4. 45. E. Lat. 49. 32. 43. N.

OLNEY, a market-town in the hundred of Newport, in the county of Buckingham, fifty-six miles from London. It is built on the river Ouse, and consists chiefly of one long street. The only distinguished object is the parish church, a spacious building, with a spire 185 feet in height, being the most lofty of any in the county. There was formerly considerable occupation here for females in making bone lace; but it has nearly ceased, and been feebly replaced by making straw-plaiting for hats. This place was the residence of the poet Cowper, who drew much of his descriptions from the scenery around the town. There is a market on Monday, but it has much declined. The population amounted in 1801 to 2075, in 1811 to 2268, in 1821 to 2339, and in 1831 to 2418.

OLONEZ, a government or stadtholderate of Russia, so called from the city of the same name, and also the river which empties itself into the Lake of Ladoga. It extends in north latitude from 60. 29. to 66. 30., and in east longitude from 29. 45. to 41. 37., and has a superficies of 83,314 square miles. It is very thinly peopled, containing not more than 350,000 inhabitants. The southern part of the province is level, and abounds in lakes and morasses, including in the former the large Lake of Ladoga. In the northern part a portion of the Scandinavian range of mountains enters from Sweden and Norway. The soil is generally sterile, and the climate ungenial; but the former produces some rye, barley, and oats, though the harvests rarely afford four times the quantity of seed that is sown. The most important products, besides grain, are derived from the forests, which are extensive, and, besides fuel, supply timber for building, as well as tar and pitch. There are some few mines of iron worked, and the quarries yield marble and other kinds of stone, enormous blocks of which are conveyed to St Petersburg for building. The province is divided into eight circles, which contain eight cities and 227 parishes.

OLOT, a large town in the north-east of Spain, in the province of Catalonia and district of Vique. It is situated on the river Fluvia, about twenty miles to the north-west of the city of Gerona, so celebrated for its gallant defence against the French. It is surrounded with walls, is tolerably well built, with several squares, and contains three parochial and two conventual churches, besides a large hospital. In the town there are 3000 houses, and about 15,000 inhabitants, and it is one of the most industrious places in the kingdom. It is particularly distinguished by its manufactures of silk goods, and of cotton and woollen stockings. It has, too, several establishments for making serges and corduroys, as well as coarser woollens; some mills for spinning cotton, several tanneries, some printed cotton works, several soap-making manufactories, and a large manufactory of cards. It also has a considerable trade in cork and in wool. Notwithstanding it has suffered severely by the loss of the trade to South America, and by the internal political dissensions, it has made considerable progress in all branches of industry.

OLPAR, a town of Hindustan, in the province of Gujerat, and district of Broach, seven miles north from Surat. Long. 73. 1. E. Lat. 21. 18. N. It is also a small district, which was settled as a private estate on the peishwa, by the Mahratta treaty of 1803, but was afterwards taken from him on account of his treacherous conduct.

OLUTORA, a river of Asiatic Russia, which falls into the Eastern Ocean near the peninsula of Kamtschatka. A fort has been constructed by the Russians on its bank, but this has been twice destroyed by the Koriaks, a singular race, who take the whale in nets formed of thick ropes.

OLYMPIA, in *Ancient Geography*, was surnamed Pisatis, and so called from the territory of Pisa, in Elis. According to Strabo, there was here the temple of Jupiter Olympius, before which stood a grove of wild olive trees, in which was the stadium or foot-course, so called because it was the eighth part of a mile; and by it runs the Alpheus, which comes down from Arcadia. Olympia, however, was famous not merely for the temple of Jupiter, but also for a temple of Juno, sixty-three feet in length, with columns of the Doric order round it; and a metroum, or temple of the mother of the gods, a large Doric edifice, with holy treasuries. These, and the porticoes, gymnasium, prytaneum, and many more buildings, chiefly in the enclosure, with the houses of the priests and other inhabitants, rendered Olympia a place of no inconsiderable importance. The stadium was in the grove of wild olive trees, before the great temple; and near it was the hippodrome, or course for the races of horses and chariots. The Alpheus flowed by from Arcadia, in a copious and pleasant stream, which was received on the coast by the Sicilian Sea.

The temple of Jupiter was of the Doric order, sixty-eight feet in height to the pediment, ninety-five in width, and two hundred and thirty in length; the cell being encompassed with columns. It was erected with the stone of the country; but the roof was of Pentelican marble, the slabs being disposed as tiles, and the access to it was by a winding staircase. The two pediments were enriched with sculpture, one having over the centre a statue of Victory gilded, and underneath a votive buckler of gold. At each corner there was a gilded vase. Above the columns were fixed twenty-one gilded bucklers, offered at the conclusion of the Achæan war by the Roman general Mummius. The gates in the two fronts were of brass, and over them were carved the labours of Hercules. Within the cell were double colonnades, between which was the approach to the image.

The Jupiter of Olympia was accounted alone sufficient to immortalize its sculptor Phidias. It was of ivory and gold, and the head was crowned with olive. In the right hand was a statue of Victory; and in the left a flowered sceptre, composed of various metals, and on which was an eagle. The sandals were of gold, and the vestment was of the same material, being curiously embossed with lilies and animals. The throne was gold inlaid with ebony and ivory, and studded with jewels, intermixed with paintings and exquisite figures in relief. The pillars between the feet contributed to its support. Before it were walls, serving as a fence, and decorated principally with the exploits of Hercules; the portion opposite to the door was of a blue colour. A family descended from Phidias, and called *phædruntæ*, or *the polishers*, had the charge of keeping the work bright and clean. The veil or curtain was of cloth rich

Olympiad ‖ Olympic Games.

with the purple dye of Phœnicia, and worked with Assyrian embroidery; an offering of King Antiochus, and which was let down from above by loosening the strings. The image impressed the spectator with an opinion that it was wider and higher than it actually measured. Its magnitude was such, that, though the temple was very large, the artist seemed to have erred in the proportions. The god, sitting, nearly touched the ceiling with his head, and thus suggested an idea that, if he were to rise up, he would destroy the roof. A part of the pavement before it was of black marble, enclosed in a rim of Parian or white marble, within which they poured oil to preserve the ivory.

The altar of Jupiter Olympius was of great antiquity, and composed of the ashes of the thighs of the victims, which were carried up and consumed on the top of it, along with wood of the white poplar tree. The ashes also of the prytaneum, in which a perpetual fire was kept burning on a hearth, were removed annually on a fixed day, and spread upon it, being first mingled with water from the Alpheus. The cement, it was affirmed, could be made of that fluid only, and therefore this river was much respected, and esteemed the most friendly of any to the god. On each side of the altar there were stone steps, and its height was about twenty-two feet. Women and girls, when allowed to visit Olympia, were suffered to ascend the basement, which was an hundred and twenty-five feet in circumference. The people of Elis sacrificed daily, and private persons as often as they chose. Olympia was situated upon an eminence, between two mountains called Ossa and Olympus.

OLYMPIAD, the space of four years, by which the Greeks reckoned time. According to the most accurate and learned computation of the moderns, the first Olympiad fell exactly 776 years before the first year of Christ, or 775 years anterior to his birth, in the year of the Julian period 3938, and twenty-two years before the building of the city of Rome. The games were exhibited at the time of the full moon next after the summer solstice; therefore the Olympiads were of unequal length, because the time of the full moon differs eleven days every year; for which reason they sometimes began the next day after the solstice, and at other times four weeks afterwards. The computation by Olympiads ceased, as some suppose, after the 304th, in the year 440 of the Christian era. It was universally adopted, not only by the Greeks, but by many of the neighbouring countries; though the Pythian games still served as an epoch to the people of Delphi and to the Bœotians, the Nemæan games to the Argives and Arcadians, and the Isthmian to the Corinthians and the inhabitants of the isthmus. To the Olympiads history has been greatly indebted. They have served to fix the time of many momentous events; and indeed before this method of computing time was observed, every page of history is mostly fabulous, being filled with such obscurity and contradiction, that no true chronological account can be properly established or maintained with certainty.

OLYMPIC GAMES were solemn games amongst the ancient Greeks, and so called from Olympian Jupiter, to whom they were dedicated. By some they are said to have been first instituted by him after his victory over the sons of Titan; whilst others ascribe their institution to Hercules (not the son of Alcmena, but one of much greater antiquity), others to Pelops, and others to Hercules the son of Alcmena. The festival, which lasted five days, began and ended with a sacrifice to Olympian Jupiter. The intermediate time was chiefly filled up by the gymnastic exercises, in which all freemen of Grecian extraction were invited to contend, provided they had been born in lawful wedlock, and had lived untainted by any infamous or immoral conduct. The preparation for this part of the entertainment was made in the gymnasium of Elis, a spacious edifice surrounded by a double range of pillars, with an open area in the middle. Adjoining were various apartments, containing baths, and other conveniences for the combatants. The neighbouring country was gradually adorned with porticoes, shady walks, and groves, interspersed with seats and benches; the whole being originally destined to relieve the fatigues and anxiety of the candidates for Olympic fame, and frequented in later times by sophists and philosophers, who were fond to contemplate wisdom and communicate knowledge in those delightful retreats. The order of the athletic exercises, or combats, was established by Lycurgus, and corresponded almost exactly to that described by Homer in the twenty-third book of the Iliad, and the eighth of the Odyssey. Iphitus, we are told, appointed the other ceremonies and entertainments; settled the regular return of the festival at the end of every fourth year, in the month of July; and gave to the whole solemnity that form and arrangement which it preserved with but little variation for more than a thousand years; a period exceeding the duration of the most famous kingdoms and republics of antiquity. Amongst the benefactors of Olympia at a much later period was reckoned Herod, afterwards king of Judæa. On his way to Rome, seeing the games neglected or dwindling into insignificance, from the poverty of the Eleans, he displayed great munificence as president, and provided an ample revenue for their future support and dignity. Such an institution, even in its least perfect form, must have been attended with advantages to society. It is sufficient to mention the suspension of hostilities which took place, not only during the celebration of the festival, but for a considerable time both before and after it. Considered as a religious ceremony, to which the whole Grecian race was invited, and even enjoined to assist in its celebration, it was well adapted to facilitate intercourse, to promote knowledge, to soften prejudice, and to accelerate the progress of civilization. Greece, particularly Peloponnesus, was the centre from which the adventurous spirit of its inhabitants had diffused innumerable colonies throughout the surrounding nations. To these widely-separated communities, which, notwithstanding their common origin, seemed to have lost all connection and correspondence, the Olympiad served as a common bond of alliance and a point of re-union. The celebrity of this festival continually attracted to it the characters most distinguished for genius and enterprise, whose fame would have otherwise been unknown and lost in the extent of the Grecian territory. The remote inhabitants, not only of European Greece, but of Asia and Africa, being assembled at the worship of their common gods, were thus trained to the sense of a general interest, and excited to the pursuit of national honour and prosperity. Strangers of similar dispositions might confirm in Elis the sacred and indissoluble ties of hospitality. If their communities were endangered by any barbarous power, they might there solicit assistance from their Grecian brethren; and, upon other occasions, they might explain the benefits which, in peace or war, their respective countries were best qualified to communicate. And thus the Olympic festival might serve the purpose of resident ambassadors, and of other institutions alike unknown to antiquity.

Om ‖ Omar Ebn al Khattab.

OM, a considerable river of Tobolsk, in Asiatic Russia, which rises in a lake, and, after a western course of about 500 miles, falls into the Irtysch.

OMA, one of the Molucca Islands, about nine miles in length and six in width, containing about 5000 inhabitants.

OMAR EBN AL KHATTAB, the successor of Abu-Bekr. We are informed that Omar was miraculously converted to the Mahommedan faith. Before this event he is said to have been truly respectable, and in particular a violent opposer of the Arabian prophet. Mahommed, it seems, felt this opposition, and regretted it; he, therefore, with all the fervour, and, as it happened, with all the success of a true prophet, as his followers pretend, prayed for the conversion of his dangerous antagonist. Omar is said to have no sooner read the twentieth chapter of the Koran than he was convinced; upon which he instantly repaired to Mahommed and his followers, and declared his conversion. On the death of Abu-Bekr, who had succeeded the impostor himself, he was promoted to the regal and pontifical dignity. The title first assigned him was the "caliph of the caliph of the apostle of God;" or in other words, "the successor of the successor of Mohammed;" but the Arabs, considering that this title, by the addition to be annexed to it at the accession of every future caliph, would be too long, they, by universal consent, saluted him "the emperor of the believers;" which illustrious title, conferred at this juncture upon Omar, descended afterwards to all the successors of that prince. He was assassinated by a Persian slave, who stabbed him in the mosque at Medina. This event took place in the twenty-third year of the Hegira, which began in the year of Christ 643. His extensive conquests rendered the Moslem empire one of the most powerful and formidable monarchies in the world.

OMBAY, an island in the Eastern Seas, forty-five miles in length and about thirteen in breadth. Its inhabitants are fierce and treacherous in their habits, so that it is dangerous for strangers to approach it. It is twenty miles west of Timor.

OMBRE, a well-known game at cards, borrowed from the Spaniards, and played by two, by three, or by five persons, but generally by three. When three play at this game, nine cards are dealt to each party; the whole ombre pack being only forty, because the eights, nines, and tens are thrown out of the pack. There are two sorts of counters for stakes, the greater and the lesser. The last has the same proportion to the other as a penny has to a shilling. Of the greater counters each man stakes one for the game; and one of the lesser for passing for the hand, when eldest, and for every card taken in. As to the order and value of the cards, the ace of spades, called *spadillo*, is always the highest trump, in whatsoever suite the trump be; the *manille*, or black deuce, is the second; and the *basto*, or ace of clubs, is always the third. The next in order is the king, the queen, the knave, the seven, the six, the five, four, and three. Of the black there are eleven trumps, and of the red, twelve. The least small cards of the red are always the best, and the most of the black, except the deuce and red seven, both of which are called the *manilles*, and are always second when the red is a trump. The red ace, when a trump, enters into the fourth place, and is called *punto;* otherwise it is only called an ace. The three principal cards are called *matadores*, and have this privilege, that they are not obliged to attend an inferior trump when it leads; but, for want of a small trump, the person may renounce small trumps, and play any other card; and when these are all in the same hand, the others pay three of the greatest counters a piece. With these three for a foundation, the player may count as many matadores as he has cards in an uninterrupted series of trumps; and for all these the others are to pay one counter a piece. He who has the first hand is called *ombre*, and has his choice of playing the game, of naming the trump, and of taking in as many or as few cards as he pleases; and after him the second, &c. But if he does not name the trump before he looks on the card which he has taken in, any other may prevent him, by naming what trump he pleases. He who has the first hand should neither take in nor play, unless he has at least three sure tricks in his hand; for, as he wins the game who wins most tricks, he that can win five of the nine has a sure game. This is also the case if he win four, and can so divide the tricks that one person may win two, and the other three.

If a person play without discarding or changing any of the cards, this is called playing *sans prendre;* and if another win more tricks than he, he is said to win *codille.* The oversights in the course of the game are called *beasts;* and if the ombre wins all the nine tricks, it is called winning the *vole.*

In ombre by five, which many, on account of its not requiring so close an attention, prefer to that by three, only eight cards a piece are dealt; and five tricks must be won, otherwise the ombre is beasted. Here the person who undertakes the game, after naming the trump, calls a king to his assistance; upon which the person in whose hand the king is, without discovering himself, is to assist him as a partner, and to share his fate. If, between both, they can make five tricks, the ombre wins two counters, and the auxiliary king only one; but when the counters are even, they divide them equally. If the ombre venture the game without calling in any king, this too is called playing *sans prendre;* in which case the other four are all against him, and he must win five tricks alone, or be beasted. The rest is much the same as by three.

OMBROMETER, an instrument to measure the quantity of rain that falls. It consists of a tin funnel, the surface of which is an inch square, with a flat board, and a glass tube set into the middle of it in a groove. The rise of the water in the tube, the capacity of which at different times must be measured and marked, shows the quantity of rain that has fallen.

OMEERSEER, a village of Hindustan, in the province of Cutch, about four miles south from Luckput Bunder. Lat. 23. 43. N.

OMELET, or OMELETTE, a kind of pancake or fricassée of eggs, with other ingredients, very common in Spain and in France.

OMEN is a word which, in its proper sense, signifies a sign or indication of some future event, taken from the language of a person speaking without any intention to prophecy. Hence Tully says that the Pythagoreans attend to the discourse, not only of gods, but also of men, which they call *omens.* This sort of omen was supposed to depend much upon the will of the person concerned in the event; and hence the phrases, *accepit omen, arripuit omen.* Such were the original omens: but they were afterwards derived from things as well as from words. Thus Paterculus, speaking of the head of Sulpicius on the rostrum, says it was *velut omen imminentis proscriptionis*, the omen of an impending proscription. Suetonius observes of Augustus, that he believed implicitly in certain omens; and that if his shoes were improperly put on in the morning, especially if the left shoe was put upon his right foot, he considered it as a bad omen. Omen was used, in a still larger sense, to signify an augury, as in the following line of Tully: "Sic aquilæ clarum firmavit Jupiter *omen*," thus Jove confirmed the bright omen of the eagle. Lastly, it was used, in the most generic sense of all, for a portent or prodigy; as in the third book of the Æneid, where a myrtle torn up by Æneas dropped blood.

The portentous or supernatural omens were either external or internal. Of the former kind were those showers of blood so frequently occurring in the Roman history, which were much of the same nature with this adventure of Æneas, which he calls *monstra deum.* Of the latter kind were those sudden consternations, which, seizing upon men without any visible cause, were imputed to the agency of the god Pan, and hence called *panic terrors.* But indeed there was hardly any thing, however trivial, from which the ancients did not draw omens. That it should have been thought a direful omen when any thing befell the temples, altars, or statues of the gods, need therefore excite no wonder; but that the meeting of an eunuch, a negro, a bitch with whelps, or a snake lying on the road, should have been looked upon as portending bad fortune, is a deplorable instance of human weakness, and of the pernicious influence of superstition on the mind.

It is more than probable that this practice of making ordinary events ominous of good or bad fortune took its rise in Egypt, the parent land of almost every superstition; but wherever it may have arisen, it spread itself over the whole inhabited globe, and at this day prevails in a greater or less degree amongst the vulgar of all nations. The following may be cited as examples.

To break a looking-glass is extremely unlucky; the party to whom it belongs will lose his best friend. If, going a journey on business, a sow cross the road, you will probably meet with a disappointment, if not a bodily accident, before you return home. To avert this you must endeavour to prevent her crossing you; and if that cannot be done, you must ride round on fresh ground. If the sow be attended with her litter of pigs, it is lucky, and denotes a successful journey. It is unlucky to see first one magpie, and then more; but to see two denotes marriage or merriment; three, a successful journey; four, an unexpected piece of good news; and five, that you will shortly be in a great company. To kill a magpie will certainly be punished with some terrible misfortune. If in a family the youngest daughter should be married before her elder sisters, they must all dance at her wedding without shoes. This will counteract their ill luck, and procure them husbands. If you meet a funeral procession, or if one pass by you, always take off your hat. This keeps all the evil spirits attending the body in good humour. If, in eating, you miss your mouth, and the victuals fall, it is very unlucky, and denotes approaching sickness. It is lucky to put on a stocking the wrong side outwards; changing it alters the luck. When a person goes out to transact any important business, it is lucky to throw an old shoe after him. It is unlucky to present a knife, scissors, razor, or any sharp or cutting instrument, to one's mistress or friend, as they are apt to cut love and friendship. To avoid the evil effects of this, a pin, a farthing, or some trifling recompense, must be taken. To find a knife or razor denotes ill luck and disappointment to the party that finds it.

OMER, St, an arrondissement of the department of the Pas de Calais, in France. It extends over 450 square miles, and comprises seven cantons and 136 communes, with 105,020 inhabitants. The capital is the city of the same name, situated on the river Aa. It has walls, broad streets, and well-built houses, a cathedral, six churches, a college, 2100 houses, and 19,032 inhabitants. It is a place of considerable manufactures of woollens, and where, by means of a canal connecting it with the city of Calais, there is a great internal trade in agricultural products. Long. 2. 9. 52. E. Lat. 50. 44. 52. N.

OMERCUNTUC, a district and town of Hindustan, in the province of Gundwana. It is a celebrated resort of Hindu pilgrimage. In the neighbourhood are found the sources of the three great rivers, the Soane, Nerbuddah, and the Mahanuddy, which adds to the sanctity of the place; the Hindus always evincing a great regard for the sources and the confluence of rivers. Long. of the town 82. 15. E. Lat. 22. 53. N.

OMERPOOR, a town of Hindustan, in the nizam's territories, in the province of Berar, eighty-two miles north-east from Julnapoor. Long. 77. 10. E. Lat. 20. 23. N.

OMMON, a district of Arabia, which comprises a portion of the southern coast extending from its eastern extremity of Rasalgate to the entrance of the Persian Gulf. In the interior it is one of the wildest parts of the country, and is little known, but is generally supposed to consist of sandy deserts. Along the coast the country is more fertile, and the inhabitants are an industrious and active race, pursuing with ardour both commerce and navigation. The soil is well watered by the rivers which flow from the ranges of mountains along the coast. Its produce is confined almost exclusively to dates and a little wheat, which appears to be scarcely sufficient for its own consumption, as, according to Frazer (see Narrative of a Journey into Khorassan, p. 17), large quantities of the latter article are imported from Bushire and Bassora. On the other hand, large quantities of dates are also exported; those of Ommon enjoying, it is said, a preference over the produce of other places, particularly in Sinde, to which they are exported. Dates are the great staple of these countries, being the staff of life; and they are the standard by which the value of landed estates is estimated. Landed property, although it usually descends by inheritance, may be disposed of in any way the proprietor pleases. The sovereign's claim is confined to the tenth of the produce, and he can in no way interfere with the proprietor's rights, although he may divest him of any command which he possesses, or expel him from the district if he pleases. Lands are usually let out in lease, or annual rent payable in a portion of the produce. Slaves are made use of here, as throughout Arabia, in the labours of agriculture; but they are treated with kindness and indulgence. The property of the Arabs which they possess independently of land, consists for the most part in live stock, sheep, goats, camels, asses, a few horses, and cows; camels being in value from thirty to three hundred dollars a-piece, according to blood and quality. The asses of Ommon are celebrated as the finest of Arabia; and individuals of the best breed sell for very extravagant sums. The value of the common kind varies from one to forty dollars; goats from four to six dollars; sheep from one and a half to six dollars. No mules are reared, nor are horses abundant in the province. The cows have humps, and resemble those of India. Milk, butter, and ghee are very abundant, and good of their kinds; which is the more remarkable, as the cattle have little or no pasture in the neighbourhood, and are fed upon dried fish a little salted, of which they become very fond. Ommon is by no means celebrated for its manufactures, which consist of turbans and waistbands, or girdles of cotton and silk, striped or checked with blue, and having the ends ornamented with red, green, or yellow borders; cloaks, called abbas, made of sheep's wool or camel's hair, and of various degrees of fineness; cotton canvass, gunpowder, and arms of no superior quality; and earthen jars for the market of Zanguebar. They also prepare a sweetmeat in high esteem, called *hulwak*, from honey or sugar, the gluten of wheat and ghee, with a few almonds; and sharks' fins and dried salt-fish for the eastern markets. Frazer states, that the provinces of Arabia, of which Muscat is the first, are too poor to consume much foreign produce, or to afford any considerable quantity of their own in exchange. Still, he adds, there is a certain demand for many Indian productions and other articles, as rice, sugar, spices, cotton cloths, silk, indigo, ship timber, and coffee from Mocha, cowries, ivory, Joarree grain, gums, civet oil for burning, cocoa-nuts, wood for building, and slaves from Zanguebar and other African ports; dates, rose-water, &c. from Bushire and Bassora. A considerable quantity of these articles is sent to this country merely in transit, as it is a great entrepôt of the commerce which is carried on between India, Arabia, Persia, and Eastern Africa; but no inconsiderable portion is consumed in the country, and paid for chiefly in dollars and cowries; and he is at a loss to understand where this quantity of specie is procured. But it is obvious that the country can only procure it by the sale of its own produce. There is no other source from which it can be obtained; nor need a passing traveller be surprised that he cannot comprehend at a glance all the resources which an extensive district may possess for carrying on foreign trade. Where can any country find equivalents to exchange with foreigners for their produce but within itself? The fact stated by Mr Frazer, of the abundance of specie given in exchange for foreign articles, speaks for itself. It is an index of the state of wealth; nor need it excite the smallest incredulity or surprise. The climate of Ommon is extremely unfavourable for European constitutions; scarcely any native of Europe ever resides here without experiencing its fatal effects. The heat is always great. Frazer mentions, that during his abode there, which was in July, the heat varied from 90° to 102° of Fahrenheit; the greatest inconvenience experienced was from the suffocating heat of the nights, as a parching wind blew from the rocks, preventing that cool freshness which the dewy morning brings in most countries, and keeping the frame so continually relaxed and unrefreshed by sleep, as to render it predisposed to the attacks of disease. The natives are the most expert navigators in these seas, and use a very singular species of craft, which are broad in proportion to their length, and are constructed of planks fastened together by nails, and tied and sewed together with cords. This country was early invaded by the Portuguese, who acquired possession of Muscat, its principal port, which they retained for nearly two centuries. Ommon was invaded and conquered, in the course of the last century, by Nadir Shah. But the native princes, when his armies were engaged in other quarters, took the opportunity of re-conquering their dominions, which they have ever since retained. The chief towns are Rostak, the residence of the imaum; Muscat, which is chiefly known to Europeans; and Kalhat and Sohar.

The country is ruled by a supreme chief or imaum, who, besides, holds in possession the islands of Keshmee and Ormuz in the gulf, and rents from the court of Persia Gomberoon, and Binderabbassec and its dependencies, including the district of Juroom, which extends from Meenab, on the south-east, to Khumeer, on the north-west, including about eighty miles of sea-coast. His revenues are derived from various sources. He receives a tenth part of the produce of the territories of Ommon, which is trifling; a duty of a half per cent. on all merchandise passing up the gulf on Arab bottoms, amounting, according to Frazer's estimate, to 160,000 dollars a year; the rents of valuable sulphur mines, which he holds of the Persian government; and considerable landed property in the country of Ommon, which brings him in only some thousands of dollars in the year. Commerce is perhaps the chief source of his income. He possesses five fine ships, his private property, two of them mounting fifty and forty guns respectively, besides four other vessels such as are used on the Arabian coast. His vessels trade to all parts of India and the East, to the coasts of Arabia and Africa, to Madagascar and the Mauritius, besides the ports of the Persian Gulf.

OMOA, a Spanish town and fortification on the southern side of the Bay of Honduras. Long. 89. 50. W. Lat. 15. 50. N.

OMOPHAGIA, an ancient Greek festival in honour of Bacchus, surnamed *Omophagos*, or the eater of raw flesh. This festival was observed in the same manner with the other festivals of Bacchus, in which the celebrants counterfeited madness. What was peculiar to it was, that the worshippers used to eat the entrails of goats, raw and bloody, in imitation of the god, who was supposed to have done the same thing.

OMPHALE, in fabulous history, a queen of Lydia, the daughter of Jardanus. She married Tmolus, who at his death left her mistress of his kingdom. Omphale having been informed of the great exploits of Hercules, wished to see so illustrious a hero; and her wish was soon gratified. After the murder of Eurytus, Hercules fell sick, and was ordered to be sold as a slave, that he might recover his health and the right use of his senses. Mercury was commissioned to sell him, but Omphale bought him, and restored him to liberty. The hero became enamoured of his mistress, and the queen having favoured his passion, had a son by him, whom some call Agelaus, and others Lamon. From the son in question were descended Gyges and Crœsus; but this opinion is different from the account which represents these Lydian monarchs as having sprung from Alcæus, a son of Hercules by one of the female servants of Omphale. Hercules is represented by the poets as so desperately enamoured of the queen, that, to conciliate her esteem, he span by her side amongst her women, whilst she covered herself with the lion's skin, seized the club of the hero, and often struck him with her sandals for the uncouth manner in which he held the distaff.

OMRATTEE, a large, fortified, and trading town of Hindustan, in the province of Berar. It carries on an extensive trade in cotton, which is sent to Mirzapore by land carriage, a distance of 500 miles, and is sold in this celebrated mart for quadruple its original cost. Long. 78. 20. E. Lat. 20. 59. N.

OMREE, a town of Hindustan, in the province of Berar, belonging to the nizam. Long. 77. 64. E. Lat. 21. 7. N.

OMSK, a town of Asiatic Russia, in the government of Tomsk, situated at the junction of the river Om with the Irtysch. It is intended as a barrier against the incursions of the Kirghises. It is an agreeable town, and the general's house, the church, and the military school, are handsome edifices. It has always a garrison, and the inhabitants amount to 800. It is deficient in a supply of wood, which the coldness of the climate renders almost a necessary of life. The original fort was built in 1716, but was transferred to its present site in 1766. Long. 74. 54. E. Lat. 55. 4. N.

OMUDWARA, a district of Hindustan, in the Mahratta territories, and province of Malwah. It is a wild and uncultivated country, much covered with jungle; but where cultivated it is of great fertility, being intersected by the Sopra and Gilligsind Rivers.

ON, in *Ancient Geography*, a city of ancient Egypt, sacred to the sun, and on that account called by the Greeks *Heliopolis*. It was remarkable for the wisdom and learning of its priesthood, and for the spacious building in which they cultivated the studies of philosophy and astronomy. The priests of On were esteemed more noble than all the other priests of Egypt. They were always privy councillors and ministers of state; and therefore, when Pharaoh resolved to make Joseph his prime minister, he very wisely gave him in marriage a daughter of the priest of On, thereby incorporating him into the most venerable caste in Egypt. Bishop Warburton thinks that the superior nobility of the priests of On was chiefly owing to their high antiquity and great learning. That they were much addicted to the study of astronomy, we know from the testimony of Strabo; and indeed nothing is more probable than that they should have been attached to the study of that system over which their god, the Sun, presided, not only in his moral, but also in his natural capacity. The learned prelate affirms, that whether they received the doctrine from original tradition, or invented it at hazard, which last supposition he thinks more probable, it is certain they taught that the Sun is in the centre of its system, and that all the other bodies move round it in perpetual revolutions. "This noble theory," he continues, "came with the rest of the Egyptian learning into Greece (being brought thither by Pythagoras, who received it from Œnuphis a priest of On); and after having given the most distinguished lustre to his school, it sunk into obscurity, and suffered a total eclipse throughout a long succession of learned and unlearned ages, till these times restored its ancient splendour, and immoveably fixed it on the unerring principles of science."

ONATEYA, or ONATIAYO, one of the Marquis of Mendoza's Islands, about five leagues to the east of Ohittahoo. It is three leagues in circumference, and of moderate elevation, with extensive woods and plantations. Long. 138. 55. E. Lat. 9. 55. S.

ONEEHOW, one of the Sandwich Islands, in the North Pacific Ocean, about forty miles in circumference. It contains abundance of yams, and a sweet root used by the inhabitants. The population is estimated at about 10,000.

ONEGA, a city of European Russia, in the province of Archangel. It is the capital of a circle of the same name, both so called from the river which waters a great part of the district, and at the mouth of which the city has been built. It is a small but well-built town, containing less than 2000 inhabitants, who subsist by trading in timber, pitch, and tar, and by exporting oats in some seasons to Norway. It has some trade in ship-building. It is about eighty miles from Archangel, and 916 from St Petersburg. Long. 38. 7. 40. E. Lat. 63. 53. 36. N.

ONEGA, a river and lake of the Russian empire. It is a hundred miles in length and forty in breadth, having a communication with the lake Ladoga, and consequently with St Petersburg. The river, which has its source in Cargapol, and gives its name to a country full of woods, falls into the White Sea.

ONEGLIA, a district of the province of Nice, in the kingdom of Sardinia, bounded on the south-east by the Gulf of Genoa, and on the other sides by the territory forming a part of that ancient republic. It is about ninety square miles in extent, and is almost covered with olive trees, which yield abundance of oil; besides which, wine, figs, silk, flax, and some corn, are produced. It was formerly considered as a principality, and gave the title of prince to the family of Doria. The principality was divided into three valleys; Oneglia, Maro, and Prela. The capital, bearing the name of the district, is about one mile to the eastward of Port Maurice, and a mile and three quarters from Cape Verde. It stands upon a plain on the sea-shore, and the river Impero falls into the Mediterranean Sea on its western side. It is surrounded with walls, and defended by three forts; one in the centre, and one at each end. The anchorage-ground is good, but open to the prevailing winds. There are several religious houses for both sexes, a gymnasium, and a governor's palace. It contains about 4000 inhabitants. Long. 8. 2. E. Lat. 43. 53. N.

ONEIROCRITICA, the art of interpreting dreams, or a method of foretelling future events by means of dreams. The word is formed from the Greek ὀνειρος, *a dream*, and κριτικη, from κρισις, *judgment*. Some call it *oneirocratica*, and derive it from ὀνειρος, *a dream*, and κρατεω, *I possess*, or *I command*. It appears from several passages of Scripture, that, under the Jewish dispensation, there was such a thing as foretelling future events by dreams; but then a particular gift or revelation was expressly required for that purpose. Hence it has been inferred, that dreams are really significative, and forebode something to come; and all that is wanting amongst us is the *oneirocritica*, or the art of knowing what they foreshow. Yet it is the opinion of many that dreams are mere chimeras, bearing indeed some relation to what has passed, but none at all to what is to come. As to the case of Joseph, it was possible for God, who knew all things, to discover to him what still remained hidden in the womb of fate; and to introduce that disclosure, he might take the occasion of a dream.

ONEIROCRITICS, a title given to the interpreters of dreams, or those who judged of events from the circumstances of dreams. No great regard is to be paid to those Greek books called *oneirocritics;* nor do we know why the patriarch of Constantinople, and others, should have amused themselves with writing on so pitiful a subject. Rigault has given us a collection of the Greek and Latin works of this kind; one attributed to Astrampsichus, and another to Nicephorus, patriarch of Constantinople; and to these are added the treatises of Artemidorus and Achmet. But the books themselves are little else than reveries; a kind of waking dreams, to explain and account for sleeping ones. According to them, all the secrets of oneirocriticism consists in the relation supposed to exist between the dream and the thing signified; but they are far from keeping to the relations of agreement and similitude, and frequently have recourse to others of dissimilitude and contrariety. Concerning oneirocritics and oneirocritica, the unlearned reader will find much information in Warburton's Divine Legation of Moses, and in the works to which he refers.

ONEVY, one of the Friendly Islands, in the Southern Pacific Ocean, near the north coast of Tongataboo.

ONGOLE, a district and town of Hindustan, in the province of the Carnatic, situated between the 15th and 16th degrees of north latitude. It was formerly dependent upon the principality of Cuddapah, and was afterwards incorporated with the Carnatic below the Ghauts, and in consequence came under the dominion of the nabob of Arcot, by whom it was transferred to the British in 1781. The principal rivers are the Mussy and the Gondegamma; and the chief towns are Ongole, Courchier, and Sintalsheroo. Ongole was formerly a fortified town; but the fortifications, owing to the tranquil state of the country, have now been allowed to go to decay. It is 173 miles north by west from Madras. Long. 81. 1. E. Lat. 15. 31. N.

ONGOLOGUR, a town of Hindustan, possessed by independent zemindars, in the province of Orissa, fifty-five miles west from Cuttack. Long. 85. 20. E. Lat. 20. 36. N.

ONKELOS, surnamed the *Proselyte*, a famous rabbi of the first century, and author of the Chaldaic Targum on the Pentateuch. He flourished in the time of Jesus Christ, according to the Jewish writers, who all agree that he was, at least in some part of his life, contemporary with Jonathan Ben Uzziel, author of the second Targum upon the prophets. Prideaux thinks that he was the elder of the two, for several reasons, the chief of which is the purity of the style of his Targum, in which it comes nearest to that part of Daniel and Ezra which is in the Chaldaic, and being the truest standard of that language, is consequently the most ancient, since that language, as well as others, was in a constant fluctuation, and in every age continued deviating from the original. Nor does there appear to be any reason why Jonathan Ben Uzziel, when he undertook his Targum, should pass over the law, and begin with the prophets, except it be that he found Onkelos had done this work before him, and with a success which he could not exceed.

Azarias, the author of a book entitled *Meor Enaim*, or the "light of the eyes," tells us, that Onkelos was a proselyte in the time of Hillel and Samnai, and lived to see Jonathan Ben Uzziel, one of the prime scholars of Hillel. These three doctors flourished twelve years before Christ, according to the chronology of Gauz, who adds, that Onkelos was contemporary with Gamaliel the elder, St Paul's master, who was the grandson of Hillel. However, he same Gauz, by his calculation, places Onkelos a hundred years after Christ, and, in order to adjust his opinion with that of Azarias, extends the life of Onkelos to a great length. The Talmudists tell us that he assisted at the funeral of Gamaliel, and was at a prodigious expense to render it magnificent. Prideaux observes, that the Targum of Onkelos is rather a version than a paraphrase, since it renders the Hebrew text word for word, and for the most part accurately and exactly, and is by far the best of the kind; wherefore it has always been held amongst the Jews in much greater esteem than the other Targums; and being set to the same musical notes with the Hebrew text, is thereby capable of being read in the same tone with it in their public assemblies. From the excellency and accuracy of the Targum of Onkelos, Prideaux also concludes that he must have been a native Jew, since, without having been bred up from his birth in the Jewish religion and learning, long exercised in all the rites and doctrines of both, and being also thoroughly skilled in both the Hebrew and Chaldaic languages, as far as a native Jew could be, he could scarcely have been thoroughly adequate to the work which he executed. The same author also thinks, that the representing him as a proselyte may have proceeded from the error of supposing him to have been the same with Akilas or Aquila of Pontus, author of the Greek Targum or version of the prophets and Hagiographia, and who was indeed a Jewish proselyte.

ONOMANCIA, or rather ONOMANTIA, a branch of divination, which foretells the good or bad fortune of a man from the letters in his name. Upon much the same principle the young Romans were accustomed to toast their mistresses as often as there were letters in their names. Hence Martial says,

Nævia sex cyathis, septem Justina bibatur.

ONOMATOPOEIA, in grammar and rhetoric, a figure where words are formed to resemble the sound emitted by the things signified; as the buzz of bees, the cackling of hens, or the note of the cuckoo. Resemblances of this kind are often fancied when they are not real; though, no doubt, there are in every language some words of which the sound is very like to that which those words are employed to express. Yet, to the mortification of grammarians and rhetoricians, conjunctions, which have been pronounced to be no parts of speech at all, are the only sounds uttered by men which are wholly natural, and these are fewer than is commonly supposed.

ONON, a large river of Asiatic Russia, upon the frontier of Chinese Tartary, which has its rise amongst the interior mountains, and flows north-east till it forms the Chilka, which afterwards discharges itself into the Amour. The rude tribes of the Bannats and Tungusses wander along its banks.

ONONDAGA, a post township and capital of Onondaga county, New York, a hundred and thirty miles west-north-west of Albany, and fifty miles west of Utica. It is ten miles in length by nine in breadth. Through the eastern part a broad valley extends north and south, bounded on each side by high swelling ridges. This valley, which is of rich alluvion and exuberant fertility, is watered by Onondaga Creek, which flows northward to Onondaga Lake, in the town of Salina. The post borough of Onondaga, the seat of the county buildings, is situated on a delightful eminence. The post village of Onondaga Hollow stands about one mile east of the court-house. It has an arsenal belonging to the state, and many mechanical establishments. Onondaga Castle is the chief town of the remnant of the Onondaga tribe of Indians, after whom the township has been named. It is situated three miles south of the village of Onondaga Hollow, and contains about fifty Indian houses, which are built of logs. There are about a hundred and forty persons, who annually receive a thousand dollars from the state of New York. The whole township of Onondaga in 1831 contained 5668 inhabitants, and it does not seem to be rapidly increasing.

ONORE, formerly a seaport of Hindustan, and a place of great commerce, in the province of North Canara. It is situated at the mouth of a river which communicates with a fine salt-water lake, extending nearly as far to the east as the foot of the mountains. In 1763 it was occupied by Hyder Ali, who established dock-yards for building ships of war, which were found to have been demolished by Tippoo at the time the town was recovered by the treaty of Mangalore. Part of the town has been rebuilt, and there is now a custom-house here. A trade is carried on in rice, betel-nut, pepper, cocoa-nuts, and salt fish. This trade was carried on in boats, which were much harassed by pirates from the Mahratta coast; an evil that has always existed more or less on the shores of India, but has now nearly ceased, owing to the vigilance of the British marine. No manufactures ever existed to any extent, the trade having been destroyed by Tippoo. On the first arrival of the Portuguese in India, Onore was the capital of an independent rajah, who was subdued by them. It was subsequently taken from the Portuguese by the Dutch, who appear to have relinquished it; for, in 1763, when it came into the possession of Hyder Ali, it was considered as the property of the ranee of Bednore. In 1768 it was taken by the British, and was shortly afterwards regained by Hyder. It was taken in 1783 by General Matthews, and was restored to Tippoo at the conclusion of the year. It came under the dominion of the British, with the province of Canara, when Tippoo's empire was overthrown, in 1799. Long. 74. 25. E. Lat. 14. 18. N.

ONOSANDER, a Greek author and Platonic philosopher, who wrote Commentaries on Plato's Politics, which are now lost. But his name is particularly famous for a treatise entitled Λογος Στρατηγικος, a discourse on the duties and qualities of the general of an army, which has been translated into Latin, Italian, Spanish, and French. The time when he lived is not precisely known, but he is imagined to have been contemporary with the Emperor Claudius.

ONRUST, a small island in the Eastern Ocean, on the coast of Java, and Bay of Batavia. It is nearly of a circular form, about 4800 feet in circumference. Here the Dutch had formerly fortifications and extensive works, which were destroyed by a British armament under Sir Edward Pellew, and the island is now desolate. Onrust formerly contained about 3000 inhabitants. It is nine miles north-west from Batavia.

ONTAREE, a town of Hindustan, in the province of Gundwana, belonging to an independent chief in the district of Billounjah. Long. 83. 40. E. Lat. 24. 13. N.

ONTARIO, one of the five great lakes which separate Canada from the United States, and which are the wonder and admiration of the world. It is situated between the parallels of 43. 10. and 44. 11. of north latitude, and the meridians of 76. 25. and 79. 56. of west longitude, being the most easterly of these vast inland seas. It lies nearly east and west, and is of an elliptical shape, being a hundred and seventy-two miles in length by fifty-nine and a quarter in extreme breadth, and having a circumference of about four hundred and sixty-seven miles. The depth of water varies exceedingly, from a few feet up to several hundreds. Towards the middle, attempts have been made to reach the bottom with three hundred fathoms, without striking soundings. If this be correct, the bottom must be very considerably below the level of the Atlantic Ocean; for its surface is only two hundred and thirty-one feet above tide-water at Three Rivers on the St Lawrence, and at Albany on the Hudson. The appearance of the shores of Lake Ontario exhibit great diversity. Towards the north-east part they are low, with numerous marshy places. To the north and north-west they assume a grand and lofty character, but subside again on the south to a very moderate elevation. Bordering the lake, the country is everywhere covered with woods, through the numerous openings of which frequent settlements are seen, imparting a pleasing effect, which is greatly enhanced by the white cliffs of Toronto, and the remarkable high land over Presqu'ile, called the Devil's Nose, on the north. The view on the

Ontiniente.

south is well relieved by a back ground of hills, which, after forming the precipice of the cataract, stretch away to the eastward. The crowning object of the prospect in this direction is a conical eminence towering above the chain of heights, called Fifty-Mile Hill, as denoting its distance from the town of Niagara. Along the southern border of the lake is the celebrated ridge road, or alluvial way, extending from Rochester on the Genessee, to Lewiston on the river Niagara, eighty-seven miles. It is composed of common beech sand, and gravel-stones worn smooth, and these are intermixed with small shells. Its general width is from four to eight rods, and it is raised in the middle with a handsome crowning arch, the general surface preserving a very uniform level. It is between a hundred and twenty and a hundred and thirty feet above Lake Ontario, whence it is distant from six to ten miles.

A great number of rivers flow into Lake Ontario. Towards the western part it receives the Niagara, and from this point to the St Lawrence River, which flows from the north-east part of the lake, the line dividing Canada from the United States is in the middle of the lake, so that nearly one half of it is in the state of New York. From this state it receives the Genessee, Oswego, and Black Rivers, besides a number of smaller streams, all of which have a sand bar across the entrance. There are some fine bays and inlets, where vessels of every description may find protection in bad weather. The largest of these are Chaumont, Sodus, Little Sodus, Toronto, and Braddocks, on the United States' side of the lake; and Quinte, Burlington, and many other large ones, on the Canada side. Burlington Bay is both spacious and secure; and the disadvantages of a narrow entrance and shallow water have been obviated by a canal cut across the breach, which has opened an access to the bay for lake vessels, and made it an important and interesting harbour. Hungry Bay is very conspicuous, affording good anchorage and safe shelter amongst the islands to ships of the largest size at all seasons. York and Kingston harbours belonging to Great Britain, and Sacket's harbour to the Americans, possess every natural advantage, and are considered as the best upon the lake. The two latter are strongly fortified, being the arsenals where ships of war, even of the first rate, have been constructed by both powers, and where were fitted out those powerful hostile squadrons which conferred so much consequence on the naval operations in this quarter. Lake Ontario is navigated by sloops, schooners, and steamboats; and the sea is frequently so rough, and swept by such heavy squalls of wind, that steam-boats of common size were at first not considered as fit to traverse its waters with comfort and safety. Of the many islands situated at the eastern end of the lake, Wolf or Grand Island, lying abreast of Kingston, is the most extensive, and, by being placed at the commencement of the Cataraqui River, forms two channels leading into it, which bear the names of the North or Kingston Channel, and the South or Carleton Island Channel. Stony and Grenadier Islands are situated at the eastern end, and there are some at Quinte Bay in Canada. Lake Ontario abounds with excellent fish of various kinds, the most celebrated of which are the Oswego bass, the salmon, trout, and salmon-trout. (R. R. R.)

ONTINIENTE, a large town of Spain, in the province of Valencia, in the department of San Felipe. It is an open town, in the vicinity of the mountains, but stands in a fruitful spot, and is remarkable for the salubrity of its climate. Figs are cultivated near it of good quality, of which about 7000 quintals are annually collected and sent to other districts. The hilly parts in the vicinity produce excellent pears and apples, and near them is raised the best wheat in Spain. The inhabitants amount to 11,700, who, besides cultivation, have some employment in making linen and woollen goods, paper, and copper wares. Being inland, and out of any great road, it is a place very rarely visited by foreign travellers.

ONTONG JAVA, a group of islands in the Pacific Ocean, called by Mendana, Baxos de la Candelaria. They are twenty-two in number, and are now called New Ireland. Long. 156. E. Lat. 6. 15. S.

ONYCOMANCY, or, as some persons write it, ONYMANCY, a kind of divination by means of the nails of the fingers. The word is formed from the Greek ὀνυξ, *a nail*, and μαντεια, *divination*. The ancient practice was to rub the nails of a youth with oil and soot, or wax, and to hold up the nails thus smeared against the sun, when certain figures or characters, showing the thing required, were supposed to appear upon them.

ONYX, a mineral substance usually ranked amongst gems, and which derives its name from the colour resembling that of the nail of the finger.

OOCHASEER, a town of Hindustan, in the province of Cutch, and district of Neyer, about twenty-five miles south-west from Theraud, which belongs to the chief of Morwara. It is surrounded by a thorn hedge instead of fortifications, and has a tank of bad water, with some excellent wells. Its inhabitants are low classes of Hindus.

OOCHINADROOG, a celebrated hill-fort of Hindustan, in the district of Harpoonelly. It is of great natural strength, having an abrupt ascent of very great height, particularly to the north and west, where it is almost perpendicular. It was besieged in 1793, and taken after a siege of three months, by Tippoo, who, with the cruelty of a tyrant, mutilated all the boys and youths in the fortress, most of whom died in consequence. Long. 75. 55. E. Lat. 14. 32. N.

OODEADARGAM, a town of the south of India, in the province of Mysore. It was taken by the British in the year 1800, and now belongs to the rajah of Mysore. It gives name to a celebrated pass in the mountains, and is thirty-one miles south-east of Bangalore.

OOJAIN, a celebrated city and district of Hindustan, in the province of Malwah. The district is situated between the twenty-third and twenty-fourth degrees of north latitude, and between the seventy-fifth and seventy-seventh of east longitude. The soil is in general a black vegetable mould, which is reduced during the rainy season nearly to the consistence of mud; and when it is dried by the sun it cracks in all directions, and the fissures are so wide and deep as to render travelling dangerous. Besides the city of Oojain, this district contains 175 villages. It produces the mango, guava, plantain, melon, and several varieties of the orange and lime trees.

The capital of the above mentioned district is also named Oojain, and is the principal residence of Scindia. It is situated on the Sipperah River, and is one of the most ancient cities of Hindustan, being, according to Major Rennell, the city which was known to the Greeks under the name of Ozene. It is called in the Sanscrit Ujayini, and is stated in authentic records to have been the capital of the rajah Bickermajit, a short time after the commencement of the Christian era. The ancient city was either much larger than the modern town, or it stood almost a mile to the north of it. It was overwhelmed by a violent earthquake at a time when it was the seat of empire, as well as of the arts and of learning. Its site is easily known; for, in digging to the depth of fifteen feet, brick walls, pillars of stone, and other ruins, are discovered. Adjoining these subterranean ruins there is a remarkable cavern, which consists of a long gallery, supported by pillars, with chambers excavated in each, and containing a number of figures carved on the walls, which are of granite. Amongst the ruins ancient coins are frequently found. The modern city of Oojain is of an oblong form, about six miles in circumference, and surrounded by a stone wall with round towers. This space includes some waste ground, but the inhabited part occupies the greater portion, and is much crowded with buildings and population. The houses are built of brick, and covered with tiles. The principal bazaar is a spacious and regular street, paved with stone, and having houses of two stories in height on each side. The whole of the lower story is laid out in shops, the ascent to which is by five or six steps from the street; the upper stories are the dwellings of the owners. The most remarkable buildings in the town are the mosques and temples; Scindia's temple is but a poor building, and is so surrounded by other buildings as to be scarcely observable. The southern quarter of the city is called Jeysingpoor; it contains an observatory, erected by rajah Jyesing of Jyenagur in the early part of last century. An extensive fort and citadel were founded by Mahdajee Scindia, at the distance of about two miles from the city, containing a palace. But these works were stopped at his death, and Gwalior was preferred by the reigning chief as his stronghold and place of refuge. Oojain carries on a considerable trade. From Surat are imported various kinds of European and Chinese goods, which are frequently sold here at a very low price. From Marwar are brought pearls, and quantities of assafœtida, the production of Sinde. Diamonds from Bundelcund also pass through this city on their way to Surat. The city is well supplied with provisions; and fruits, vegetables, and grain abound in all the public markets.

Oojain is a very ancient city; the rajahs who governed it are mentioned by Ferishta as early as A. D. 1008; and it was conquered by the Mahommedans about 1230. The first of the princes who reigned here was named Jyapa Scindia, who was a servant of Bajerow the peishwa, by whom, in reward for his services, the city and district of Oojain were made over to him. He was succeeded by his son Junkojee, who was murdered after the battle of Paniput, and his uncle Ranojee obtained possession of his territories. This chief left two sons, Kedjaree and Mahdajee. The latter being the more aspiring of the two, acquired possession of the sovereignty. He was a brave and active officer, and commanded a division of troops in the memorable battle of Paniput, in which he was severely wounded in the thigh. He rose afterwards to high command, and to extensive dominion. He introduced European discipline amongst his troops, by whose aid he not only rivalled in power the greatest Mahratta chiefs, but conquered a large tract of Hindustan proper, and gained possession of the capital, Delhi, with its fallen monarch, the representative of the Great Mogul. He died in 1794, without issue, leaving the whole of his possessions to his adopted son and grand nephew Dowlut Row Scindia. In the year 1803, Scindia ventured to try his strength with the British, and a war ensued, which was soon terminated by a series of signal victories gained over his imperfectly disciplined troops, by Lord Lake and General Wellesley. He was in consequence soon compelled to sue for peace, which was concluded on the 30th of December 1803, on condition that he should cede all the territory situated between the Ganges and the Jumna, and all his possessions of every description in the country to the northward of those belonging to the rajahs of Jyenagur and Joudpoor, and the ranah of Gohud. He also relinquished to the British government the fort and territory of Broach, and the fort and territory of Ahmednuggur, and all his possessions to the south of the Aguntee Hills, including the fort and district of Gondapoor, and all the other districts between that range of hills and the Godavery. Several forts, towns, and districts, were restored to Scindia. Two of the articles in the treaty, namely, the cession of the strong fortress of Gwalior, and a subsidiary force of 6000 men to be constantly stationed with Scindia, were relinquished by Lord Cornwallis, on his return to India. On the 23d of March 1804, a treaty offensive and defensive was concluded with Scindia by Colonel, afterwards Sir John Malcolm, on the part of the British government, by which Scindia agreed to receive a British subsidiary force of 6000 men, to be stationed near his frontier; and, in the event of a war, engaged to join the Company's forces with 6000 infantry and 10,000 cavalry. He also agreed to submit all the differences he might have with the peishwa to British arbitration. It was agreed that the Chumbul should henceforth be the boundary between the two states. When the war broke out with the Pindarrees, the policy of Scindia excited strong suspicions against him; in consequence of which a new treaty was concluded in 1817, in which it was agreed that he should use his utmost exertions against the Pindarees, and that he should admit British garrisons into the fortresses of Hindia and Aseerghur during the war. The territories possessed by Scindia are still very considerable, and are supposed to yield him nearly a million per annum. For further particulars respecting this prince, see the article HINDUSTAN.

OON, a town of Hindustan, in the province of Gujerat, and district of Werrear, fifteen miles north of Rahdunpoor. The town contains about 2000 tolerably well-built houses, and the palace of the rajah. It is an open town, with one long street, which is a bazaar. The chief of this town is a Hindu of a low tribe, who derives his income of 12,000 rupees a year chiefly from the plunder of his neighbours. Long. 71. 45. E. Lat. 24. 15. N.

OONAE, a small village of Hindustan, in the province of Gujerat, belonging to the Mahrattas. It has in its vicinity a remarkable hot spring, which, like all the other extraordinary phenomena of nature, is held sacred by the Hindus, and a great resort of pilgrims, who ascribe to it the most wonderful qualities.

OONARANG, a small European town and fort of Java, on the south coast, where the Dutch governor Janssens made his last stand when the island was attacked by the British general. It is eleven miles south from Samarang.

OONIARA, a town of Hindustan, in the province of Ajmeer. It is strongly fortified with a wall and round towers; the houses are mostly built of stone, and the palace is neatly constructed with a stone enclosure, surrounded by a ditch. Long. 75. 58. E. Lat. 25. 51. N.

OONOMAFOU, an island in the South Pacific Ocean, about six miles in length, and covered with verdure. It was discovered in 1616 by Schouten and Le Maire. Long. 175. 51. W. Lat. 15. 53. S.

OOREECHA, a populous town of Hindustan, belonging to the rajah of Jyenagur, in the province of Ajmeer.

OOREY, a town of Hindustan, in the province of Agra, fifteen miles west of the river Jumna. Long. 79. 35. E. Lat. 25. 58. N.

OOSCAT, a considerable town of Anatolia, in Asia Minor, situated in a hollow, surrounded on all sides by naked and barren hills. The houses are neatly constructed of brick and wood, painted like those in the other Turkish towns. The palace is a very extensive building of brick and wood, but only two stories high; and a handsome mosque has lately been erected, of hewn stone, in imitation of St Sophia. It is surrounded by a slight wall, built of sun-dried brick and mud. The inhabitants amount to 16,000, of whom the greater number are Turks, and the remainder Greeks, Armenians, and Jews. It is 110 miles east of Angora. Lat. 39. 42. N.

OOSCOTTA, a fortress of the south of India, in the province of Mysore. It was occupied by the Mahrattas in the year 1688, but was taken from them by the nabob of Cuddapah, and retaken by the Mahrattas. In 1761 it was besieged and taken by Hyder Ali; and seven years afterwards it was taken by the British, but recovered by Hyder in 1773. It fell under the power of the British in

1779, and was made over to the new rajah of Mysore along with the province. It is fifteen miles north-east of Bangalore.

OOSSOOR, or OUSOOR, a fortress of Hindustan, in the southern province of Mysore. It was first taken by the British in 1768, and again in 1791. After the death of Tippoo, this town, with the province, was made over to the new rajah of Mysore. It is twenty miles south-south-east from Bangalore. Long. 72. 52. E. Lat. 12. 41. N.

OOSTERHOUT, a market-town of the Netherlands, in the province of North Brabant, and the arrondissement of Breda. It is a considerable place for making pottery ware and tiles, and has large markets three times a year for the sale of linen cloth. It is five miles to the north of Breda, and contains 6950 inhabitants.

OOTAPALLIUM, a town and district of the south of India, in the district of Dindigul. Long. 77. 30. E. Lat. 9. 50. N.

OOTATATOOR, a town of the south of India, in the district of Tanjore. Long. 70. 58. E. Lat. 11. 7. N.

OOTRADOORG, one of the numerous fortresses with which the country of Mysore is covered. It was taken by the British in 1792. Long. 77. 17. E. Lat. 12. 56. N.

OOTRIMALOOR, a town of the south of India, in the province of the Carnatic. Long. 79. 50. E. Lat. 12. 33. N.

OPALIA, in *Antiquity*, feasts celebrated at Rome in honour of the goddess Ops. Varro says they were held on the 19th of December, which was one of the days of the Saturnalia. These two feasts were celebrated in the same month, because Saturn and Ops were husband and wife; but the vows offered to the goddess were made sitting on the ground.

OPARO, an island in the Pacific Ocean, discovered by Captain Vancouver in 1791. It consists of a cluster of high craggy mountains. The natives are estimated at 1500, who appeared to be well fed, and to have open and cheerful countenances. Long. 215. 58. E. Lat. 27. 36. S.

OPERA, a lyrical drama set to music in recitations, airs, duetts, trios, quartetts, choruses, and *finales;* preceded by an instrumental overture, and accompanied by an orchestra; and, when performed, enforced and embellished by action and declamation, and appropriate costumes and scenery. The opera appears to have originated at Florence about the end of the sixteenth century. (See Doni's works, *passim.*) The Italians divide their operas into four kinds; the *sacred opera*, the *serious opera*, the *semi-serious opera*, and the *opera buffa*, or *comic opera*. The French have their *grand' opera*, in which the whole lyrical drama is sung; and the *opera comique*, in which the singing is intermingled with spoken dialogue. The Germans have a greater variety of such distinctions of operas; as the *grand opera*, the *serious opera*, the *tragic opera*, the *heroic opera*, the *romantic opera*, the *allegorical opera*, the *military melodrama*, the *comic opera*, and some others.

Much amusing and interesting matter relative to the rise and progress of the *opera* may be found in Dr Burney's Tours, and History, in the Baron de Grimm's Correspondence, and in various German periodicals conducted by musicians. See also Arteaga, Manfredini, Signorelli, &c. For some technicalities relative to operatic music, see the article MUSIC.

OPHICLEIDE, or KEYED-SERPENT. See MUSIC.

OPHIOLOGY is composed of two Greek words, namely, ὄφις, *a serpent*, and λογος, *a discourse*, and consequently denotes that branch of zoology which treats of serpents. See REPTILIA.

OPHIOMANCY, in *Antiquity*, the art of predicting future events from the motions or habits of serpents. Thus Calchas, on seeing a serpent devour eight sparrows, with their dam, foretold the duration of the siege of Troy; and the seven coils of a serpent which was seen on the tomb of Anchises were interpreted to mean the seven years during which Æneas wandered from place to place before he arrived at Latium.

OPHIR, a country mentioned in Scripture, from whence Solomon received great quantities of gold in ships which he sent out for that purpose. The difficulty, however, is, where to fix its situation. Some have gone in search of it to the West, others to the East Indies, and a few to the eastern coast of Africa. Mr Bruce places it in the kingdom of Sofala, on the coast of Mozambique; and he supports this hypothesis with great learning and ingenuity. It was, on the other hand, strenuously maintained by Dr Doig, a learned contributor to the third edition of this Encyclopædia, that it was situated somewhere on the western coast of Africa, and that the Tarshish of Solomon was the ancient Bætica in Spain. Whether the one hypothesis or the other be the true one, it is not for us to decide. Both are plausible, and both supported by much ingenuity and erudition; but we do not think that the arguments of either writer furnish a complete confutation of those employed by the other.

OPHITES, in *Ecclesiastical History*, Christian heretics, so called both from the veneration they had for the serpent which tempted Eve, and the worship they paid to a real serpent. They pretended that the serpent was Jesus Christ, and that he taught men the knowledge of good and evil. They distinguished between Jesus and Christ. Jesus, they said, was born of the Virgin Mary, but Christ came down from heaven to be united with him; Jesus was crucified, but Christ had left him to return to heaven. They likewise distinguished the God of the Jews, whom they termed *Jaldabaoth*, from the supreme God; ascribing to the former the body, and to the latter the soul of man. They had a live serpent, which they kept in a kind of cage; and at certain times they opened the cage door, and called to the reptile. The animal came out, and mounting upon the table, twined itself about some loaves of bread, which they broke and distributed to the company, all of whom kissed the serpent. And this, by a horrid blasphemy, they called their *Eucharist*.

OPHTHALMOSCOPY, a branch of physiognomy, which deduces the knowledge of a man's temper and character from the appearance of his eyes.

OPIATES, medicines which are administered to procure sleep, whether in the form of electuaries, drops, or pills.

OPINION is that judgment which the mind forms of any proposition, for the truth or falsehood of which there is not sufficient evidence to produce science or absolute belief. That the three angles of a plane triangle are equal to two right angles, is not a matter of opinion, nor can it with propriety be called an object of the mathematician's belief; he does more than believe it, he *knows* it to be true. When two or three men, under no temptation to deceive, declare that they were witnesses of an uncommon though not preternatural event, their testimony is complete evidence, and produces absolute belief in the minds of those to whom it is given; but it does not produce science like rigid demonstration. The fact is not doubted, but those who have it on report do not know it to be true, as they know the truth of propositions intuitively or demonstrably certain. When one or two men relate a story including many circumstances to a third person, and another comes who positively contradicts it either in whole or in part, he to whom these jarring testimonies are given weighs all the circumstances in his own mind, balances the one against the other, and lends an assent, more or less wavering, to that side on which the evidence appears to preponderate. This assent is his opinion respecting the facts of which he has received such different accounts.

OPIUM, in the *Materia Medica*, is an inspissated juice, obtained from the capsule of the white poppy; it is partly of the resinous and partly of the gummy kind, and possesses also a narcotic principle.

OPOCALPASUM, Opocarbasum, or Apocalpasum, a gummy, resinous substance, which has a strong resemblance to liquid myrrh, and which in the time of Galen was mixed with myrrh. According to this writer, it was difficult to distinguish the one from the other except by their effects, the former being of a poisonous nature, and frequently producing lethargy.

OPORTO, or Porto, a city of Portugal, usually considered as the northern capital of that kingdom, and one of the most important commercial places of the peninsula. It is situated in the province Entre Douro and Minho, at the mouth of the latter river. The land near the mouth of the river is generally low, but the city, being situated on an elevation on the northern bank, may be descried at the distance of four or five leagues, by a remarkably black steeple, called Los Clerigos, which rises in the middle of it. On approaching the bar, the town and castle of St John de Foz are seen upon low land, near the mouth of the river, with a lighthouse, lighted every night. On the northern point of the castle of St John de Foz a ledge of rocks extends towards the south-west, some of them above water; and without these, on the opposite side, is a similar ledge. This formation renders the entrance difficult without much previous knowledge, especially as with winds from the south-west and the north-west a heavy sea sets in along the coast. The bar of the Douro is liable to alterations of its position from gales of wind, which makes it the more necessary to take a pilot, a matter not difficult, as there are plenty of fishermen perfectly competent, who are ready to act in that capacity. When vessels have passed the bar they are in a state of security, except at periods when, after a heavy fall of rain, such torrents rush down the Douro as to raise the water from thirty to forty feet in a few hours. These *freshes*, as they are called, have also a great influence in changing the position of the bar. The vessels that are intended for the harbour of Oporto should not, however, draw more than sixteen feet water.

As this city gives name to the whole kingdom of which it forms the second capital, a short sketch of its history may be appropriate. It is first noticed in the itinerary of the Emperor Antoninus, in the year A. D. 160, under the name Cago or Gaia, but was then on the opposite bank of the river, and defended the passage over it against the forces of Viriato. When the Goths, Vandals, Alans, and Suevi had overrun France and Spain, and attained the end of their career, the Alans entered Lusitania, and established their capital in this city, which they adorned and fortified, giving it the name of Castrum Novum, to distinguish it from Cale or Caya, the ancient part, on the opposite bank of the river, called *Castrum Antiquum*. This part of Lusitania was seized upon, about the year 540, by the Arian Goths, under their King Leovogildo, who put to the sword all who refused to embrace his opinions, and, as has been said, amongst others his own son. The Goths maintained their dominion till the invasion of the Moors in 716, when Abdulhassan overran all Galicia, and possessed himself of the whole country up to the river Douro. It fell again into the hands of the Christians, when again the Moorish chieftain Abderrahman, attacked the Catholic King Alfonso I. in 820. A desperate battle was fought at Campanha, in which the Moors were defeated, and many of them driven into the river Tinto; and a part of the city whence the Christians issued to the contest still retains the name of Batalha. Another Moorish chief subsequently conquered the city, and retained his power within it till 1092, when some Gascon knights, under the command of Don Alfonso Fredriquez, finally subdued the Moors; since which it has been retained by the Christians, and followed the fortune of the rest of Portugal.

Oporto is about two miles from the mouth of the river, on the right bank, from which it rises abruptly by an ascent, in some parts attained by a flight of 140 steps. It occupies a valley and several hills, which render some of the streets very steep. Its back or north part rests upon rocky heights, in which are quarries of granite that have yielded the stone with which the city has been built. There are many magnificent and spacious streets, well paved for foot passengers, with some fine churches, convents, and other public buildings; and these are interspersed with numerous gardens, abounding with flowers and beautiful shrubs, which give an air of great beauty to the whole place. The most remarkable edifices, as in most Catholic cities, are those devoted to religious purposes, as churches, convents, and monasteries. The most striking are very magnificently ornamented. The cathedral is a superb building, which was constructed in 1112, by Count Henrique de Porto, and the ascent to the choir is by a fine broad marble staircase. The collegiate church of Cedofeita is the next in celebrity. It is a purely Gothic structure, built in the year 559, and was left untouched by the Moors, having been redeemed from destruction by a noble family of the name of Connigos, who paid a yearly tribute for its preservation. The church of Misericordia, built in the year 1555, belongs to a corporate body, which relieves misery of all kinds, takes care of more than 2000 sick, maintains 900 foundlings, and buries those whose friends cannot afford to do so. The church of the Clerigos, built in 1748, stands at the top of a fine wide street called Calcada de Natividade. It is a superb building, most beautifully ornamented, and has a tower, before noticed, the most lofty in the kingdom, if not in Europe, which may be seen from the sea at the distance of several leagues. The other parochial churches are St Nicolao, said to be the richest, St Victoria, St Ildefonso, Santa Marinha, in Villa Nova; San Pedro; MiragayaTerco e Caridade, which is connected with a good hospital; Nosso Venhor de Bom Fim; St Pedro Gonsalvez, appropriated to the seamen; Bon Jesus de Gaya, and Senora de Lapa. Besides these, there are about eighty chapels, some of them elegantly fitted up, in which the public religious worship is celebrated. There were twelve monasteries, containing no less than 380 monks; but some of them were destroyed during the siege of Oporto by Dom Miguel, and others suffered severely. There were five convents, which contained about 340 nuns of different orders, besides numerous females who resided in them under the tuition of the nuns.

There are few cities in Europe in which the charitable institutions are more numerous than in Oporto. The public hospitals especially are extensive establishments. The principal of them is the Hospital Real, which is built of granite, and has the appearance of a palace, and is remarkable not more for its extent and grandeur than for the great number of patients which are relieved in it; they are attended by the best physicians and surgeons, both English and Portuguese, and are supplied with the best medicines, dispensed not only to the sick in the house, but also to out-door patients at half price. Of a less extent are the foundling hospital, two for unfortunate and poor females, one for beggars, one for poor old women, one for the English, and three upon a small scale distinguished by the names of St Sylva, San Crispin, and San Francesco da Carma.

This city suffered severely during the long siege which commenced in December 1833, and continued till August 1834. It was a period of severe misery to the inhabitants, as well from the constant fire kept up against the

Oporto. town, as from the scarcity of food, fuel, and other necessaries. The army of Dom Miguel had surrounded the city with works, which extended in a circuit of nearly fourteen miles, and from the forts on those lines kept up a cannonade and bombardment. The effect of the former was to make an impression upon the works of Dom Pedro, and that of the latter to destroy whatever was destructible in the houses of the inhabitants, and in the public buildings. The churches were spared by the assailants as far as their position did not interfere with the military operations. Both the public and the private buildings are constructed of massy blocks of stone, and have little combustible matter in their composition. Thus, though the windows, the decorations, and the furniture of many buildings, were much injured or destroyed, and more than sixteen thousand of the civic inhabitants killed, there was but little damage done to the interior appearance of the place; and as far as that was concerned, a very short period witnessed the restoration of the city to its former beauty. Within two years after the termination of the siege the inhabitants had in a great degree returned to those mercantile pursuits and habits which have long distinguished the city.

Oporto, in a national view, is a commercial place of the greatest importance, being the channel by which the most valuable produce of the soil of Portugal is distributed to other countries. That soil is peculiarly favourable to the growth of a strong red wine, highly relished in England, and not much esteemed in any other part of the world. It is produced from a grape originally transported from Burgundy to the banks of the Douro, whence it has spread throughout the province of Tras os Montes and the interior and higher grounds of the province Entre Douro and Minho. From the growers the wines are collected by merchants of Oporto, and preserved in large quantities till they are shipped for the markets of consumption. The best of the wines formed the subject of a monopoly to a privileged company, who possessed the right of pre-emption of a limited number of pipes before the general buyers were allowed to make their contracts. That monopoly has been abolished, a circumstance which has given a new direction to the internal trade; but the sufferings occasioned by the siege are still felt, and this, with the change of system, has made it difficult to prognosticate what may be the future condition of the wine trade in this city. One thing is certain, however, that as long as the taste for port wine continues in Great Britain as it has hitherto done, the trade of Oporto must be of the greatest importance to the kingdom of Portugal.

An Account of the number of Pipes of Wine shipped at Oporto from 1824 to 1833, distinguishing those to the British dominions from those to all other countries.

Years.	Pipes sent to Great Britain.	Pipes sent to all other Countries.	Total.
1824	19,968	6,049	26,117
1825	40,277	170	40,447
1826	18,310	287	18,597
1827	24,207	10,003	34,237
1828	27,932	13,295	41,227
1829	17,832	7,533	25,371
1830	19,333	4,832	24,165
1831	20,171	3,268	23,439
1832	13,575	2,975	16,550
1833	19,432	1,063	20,495
	231,037	49,575	270,645
Average annual export	23,103	4,957	27,064

Of the number of pipes, 49,575, sent to other countries than Great Britain in these ten years, Brazil took 28,261, the other parts of South America 8944, whilst North America, the whole of Europe, India, and Africa, took only 12,370 pipes, of which Hamburg alone received 5573. This statement shows to what an extent the north of Portugal is dependent upon the consumption of Great Britain for the chief product of its soil. A duty is collected from the wine, both on its transport from the interior, and on its exportation to foreign countries. The amount varies with the kind and quality of the wine, and is often subject to considerable fluctuation.

The other exports from Oporto consist of oil, oranges, figs, and various fruits, wool, refined sugar, cream of tartar, shumac, leather, and cork. The imported articles are, corn, rice, and other provisions; sugar and coffee from Brazil; cotton and woollen goods, hardware, tin plates, butter, and cheese, from Great Britain and Ireland; and hemp, flax, deals, and other timber, from Norway or the Baltic. It is said that a large portion of the British cottons and woollens imported at this place are for the purpose of being carried into Spain through Braganza and other frontier towns, by means of the contraband trade.

The manufactures of the city suffered exceedingly by the siege, but are now reviving. The sugar refineries are considerable; gold and silver lace is made, and also some hosiery. Cotton and linen weaving gives some occupation, as do the making of glass and paper. Though the population was reduced by the siege, it is now rapidly recovering its former state, and, by the latest calculation, amounts to about 80,000. Though somewhat cold in the winter, and therefore not so much visited by invalids as Lisbon, Oporto is generally considered as a more healthy city. The latitude, by accurate observation, is 41. 11. 15. N. the longitude 8. 8. 22. west from London.

Oppeln. OPPELN forms one of three provincial governments of Prussia, into which the province of Silesia is divided. It is bounded on the north by the government of Breslau, on the east by the kingdom of Poland and the republic of Cracow, on the south-east by Gallicia, on the south and south-west by Moravia, or rather Austrian Silesia, and on the west by the province of Reichenbach. In extent it is 5230 square miles, comprehending fifty-four cities and towns, and 1492 villages; and it is divided into fifteen circles. The population, according to the census of 1817, amounted to 529,964 individuals, and, according to that of 1826, had increased to 660,756. Of these inhabitants, about nine tenths are Catholics, and the remainder is divided into various sects. It is drained by the river Oder, into which all the streams run. The soil is not very fertile, and its most valuable produce is derived from its extensive forests. The chief industry is applied to spinning and to making wooden ware. The city of Oppeln, the capital of the province, as well as of the circle of the same name, stands on the Oder, and contains 380 houses, with 4500 inhabitants. It is surrounded with walls, and defended by a castle; and it has some trade in linen, in timber, and in ironmongery.

Oppian. OPPIAN, a Greek poet, was born at Corycia or Anazarba, in Cilicia, towards the close of the reign of Marcus Aurelius. His father, Agesilas, held a distinguished rank in the senate of his native place, not so much on account of his birth or his riches, as the credit he obtained for the extent of his knowledge and his love of philosophy, which was the object of all his studies, and the guide of all his actions. To his son he was careful to give an education conformable to his own principles, causing him to be instructed in music, geometry, and particularly the belles-lettres. The young Oppian, however, had scarcely completed his studies, when an unlooked-for reverse damped his ardour, and destroyed all his hopes. Septimius Severus, having mounted the throne, to which he had succeeded in hewing out a way with his sword, arrived at Anazarba, and immediately the senate of the place threw themselves at the feet of the conqueror. Agesilas alone, conceiving himself bound to withhold from an usurper the homage which was due only to the legitimate sovereign, stood aloof upon this occasion; a circumstance which so irritated Severus, that he deprived the philosopher of all his property, and banished him to the island of Melitus, now *Meleda*, situated in the Adriatic. Thither Oppian followed his father, and it was in this compulsory retreat that he conceived and executed his two poems on the Chase and on Fihsing, entitled *Cynegetica* and *Halieutica*. When they were finished, he went to Rome, and presented them to the son of Severus, Antoninus Caracalla, who relished them so much that he permitted the author to demand of him whatever recompense he pleased. Oppian asked only for the release of his father, with permission to the latter to return to his own country; and the emperor, as much touched with the filial affection of the son as he had been delighted with the verses of the poet, not only granted the favour he had asked, but added the gift of a gold statera (about L.1. 4s. of our money) for each one of the verses which he had just heard recited. If, as Suidas pretends, these verses amounted to twenty thousand, never did poet receive so splendid a recompense. But Oppian did not long enjoy his good fortune. Scarcely had he returned to his own country when he sunk into the grave, at the early age of thirty, having fallen the victim of a contagious malady which then desolated the city of Anazarba. His fellow-citizens erected to his memory a magnificent tomb, whereon was engraved an inscription in Greek verse, which Lorenzo Lippi has rendered as follows:

Oppianus vatum decus immortale fuissem,
Invida ni gelidum rapuisset Parca sub Orcum,
Me juvenem placidæ clarum splendore Camænæ,
Si livor longæ violasset tempora vitæ,
Non mihi laude parem quemquam terra alma tulisset.

This is all that we learn of Oppian from the anonymous Greek historian of his life, whom all the succeeding biographers have faithfully copied. We must, however, except the learned editor of his works, Schneider, who, being struck with the disparity of style which he remarked in the poems on the Chase and on Fishing, conceived that two works, which, according to him, were so different in merit, could not possibly have been the productions of the same author. Accordingly, he supposed that there were two Oppians, the first of whom, a native of Cilicia, and author of the *Halieutica*, preceded the second by several years. In the opinion of Schneider, it is to the latter that we are indebted for the *Cynegetica*, in which the author has, according to him, attempted to reproduce, but with great inferiority of talent, the manner and some of the imagery of the first Oppian. M. Belin de Ballu has, however, completely refuted this bold hypothesis, in the preface to his Greek edition of the *Cynegetica*, published at Strasburg in 1786. How, indeed, could it be reconciled with the unanimous concert of praise which critics, ancient and modern, have lavished upon this poet? John Tzetzes calls him a model of grace; J. C. Scaliger compares him to Virgil, in point of numbers, harmony, and elegance of style; Gaspar Barth, Conrad Gesner, and many others, never cite him except to couple his name with laudatory epithets. It is not easy, however, to reconcile so much praise bestowed on the one hand, and so little regard evinced for the works of Oppian on the other; nor can we help feeling some astonishment, when we consider that, from the date of the *editio princeps*, printed at Florence in 1515, two centuries elapsed before the appearance of the first really critical edition, published by Schneider in the year 1777. During this long period, it is true, there appeared several editions at considerable intervals, particularly that of Aldus, Venice, 1517, which Schneider considers as very defective, and regards as the source of all the faults which, till his time, had disfigured the text; that of Vascosan, Paris, 1549; and that of Rittershusius, Leyden, 1597. No edition appeared in the seventeenth, nor any in the eighteenth century, until the year 1777, when that of Schneider was published at Strasburg, containing the Greek text, accompanied with a Latin translation, and followed by the paraphrase in prose which the sophist Eutechnius had made of the *Ixeutica*, another poem attributed to Oppian, but which, unfortunately, has not come down to our time. This was followed by the edition of Belin de Ballu, published at Strasburg in 1786, but containing only the *Cynegetica*, of which the editor published, at the same place, the following year, a good French translation, enriched with critical notes, and a curious extract from El Doinaï's history of animals, translated from the Arabic by Baron Silvestre de Sacy, who, however, for some reason, withheld his name. Prior to this there were two French translations, one by Florent Chrestien, preceptor to Henry IV. when prince of Bearn; and another by Fermat, a counsellor of Toulouse, who, in 1690, published a prose version of the books on Hunting by Arrian and Oppian. The poem on Fishing was translated into English heroic verse by Jones and others, belonging to St John's College, Oxford, and printed there in 1722, 8vo, with a life of the author prefixed. The Latin translation of Lorenzo Lippi, printed in 1478, preceded by thirty-seven years the *editio princeps* of the Greek text. (A.)

OPPIDO, a city of Italy, in the province of Calabria Ulteriore I., in the kingdom of Naples. It stands on a hill between the rivers Modena and Trecosio, is the see of a bishop, and contains a cathedral and three other churches, with 6000 inhabitants. It suffered most severely in the earthquake of 1783, when nearly one half of the population was destroyed.

OPPILATION, in *Medicine*, the act of obstructing or stopping up the passage of the body, by redundant or peccant humours. This word is used chiefly to denote obstructions in the lower intestines.

OPOUN, the most easterly of the Navigators' Islands, in the South Pacific Ocean. Long. 169. 7. W. Lat. 14. 7. S.

OPTATIVE Mood, in *Grammar*, that which serves to express a desire or wish for something. In most languages, except the Greek, the optative is expressed by prefixing to the subjunctive a conjunction, which, with the verb, expresses the thing wished for, leaving the mind to supply the verb indicative of desire; as *utinam saperes*, "that you were wise," or, in other words, "*I wish* that you were wise."

OPTIC Angle, the angle which the optic axes of both eyes make with one another, as they tend to meet at some distance before the eyes.

Optic *Axis*, the axis of the eye, or a line going through the middle of the pupil and the centre of the eye.

OPTICS.

History.

OPTICS, from the Greek word ὀπτομαι, which signifies to *see*, is the name given to that branch of natural philosophy which treats of the nature and properties of light; of the changes which it suffers either in its qualities or in its course when transmitted through bodies, when reflected from their surfaces, or when passing near them; of the structure of the eye, and the laws of vision; and of the construction of those instruments in which light is the chief agent.

HISTORY.

The early history of optics, like that of all the sciences cultivated in ancient times, is involved in much obscurity. After the art of glass-making was discovered, lenses and spheres of glass seem to have been used as burning-glasses. In Aristophanes's comedy of *The Clouds* a burning sphere is distinctly described. Pliny speaks of globes of glass which produced combustion when held to the sun. Lactantius informs us that a globe of glass full of water could, when exposed to the sun, kindle a fire even in the coldest weather. And it appears that globes of glass were used by the Vestal Virgins to kindle the sacred fire, and by surgeons to burn the flesh of sick persons that required to be cauterised.

Aristophanes. B.C. 424. Lactantius. A.D. 303.

Among the earliest speculators on vision were Pythagoras and Plato; the former held that bodies became visible by means of particles projected from their surfaces and entering the eye, while the latter, in order to give the eye some share in the matter, supposed that something emitted from the eye met with something emitted from the object, and was again returned into the organ of vision. The followers of Plato, however, though they had deteriorated rather than improved the conclusion of Pythagoras, were acquainted with two important facts in the science. They taught that light moved in straight lines, and that when it was reflected regularly from the surfaces of polished bodies the angle of incidence was equal to the angle of reflexion.

Pythagoras. Plato.

The earliest writer on optics was Euclid, the celebrated geometer, whose treatise on the subject is still extant.[1] It consists of two books on optics and catoptrics, and proceeds on the Platonic theory, that the visual rays pass from the eye to the object, forming a cone whose apex is in the eye and whose base is the object. He shews that the angles of incidence and reflexion are equal, and that the incident and reflected rays lie in a plane at right angles to the reflecting surface; and he discusses the apparent magnitude and form of objects, and the apparent place of the images formed by reflexion from plane, convex, and concave mirrors. The book on optics contains sixty-one, and that on catoptrics thirty-one theorems.[2]

Euclid. B.C. 300.

As a naturalist Aristotle made some valuable optical observations. He described, with tolerable correctness, the phenomena of rainbows, halos, and parhelia. He considered the rainbow as produced by the reflexion of the sun's rays from the drops of rain which gave an imperfect image of the sun; and he ascribes the light which appears in the sun's absence to the reflective power of the atmosphere.

Aristotle. B.C. 410.

The speculations of Seneca and Cleomedes derive any interest they may possess from their absurdity. Seneca noticed the magnifying power of a bottle of glass in enlarging small letters, and he observed that an angular piece of glass produced all the colours of the rainbow. Cleomedes, in his cyclical theory of motion, has given an elaborate explanation of the manner in which rays proceeding from the eye render the objects which they meet visible, but it is too stupid to demand the slightest attention.

History. Seneca. A.D. Cleomedes. A.D.

The science of optics may be justly considered as owing its origin to the celebrated Claudius Ptolemy, the astronomer of Alexandria, who flourished at the end of the first century. His work entitled *Ptolemæi Opticorum Sermones quinque ex Arabico-Latine versi*, was known in the time of Roger Bacon to have treated on astronomical refractions, but it had escaped the notice of philosophers, and its valuable contents were unknown until 1816, when Delambre published an analysis of it from the manuscript in the Royal Library at Paris. Montucla had, long before the discovery of the French manuscript, mentioned that a manuscript copy of Ptolemy's Optics was in the catalogue of the Bodleian Library of Oxford. This interesting manuscript, which Professor Rigaud was so kind as to examine at our request, belongs to the Savilian Library, and had been the property of Sir Henry Savile himself. As in the Parisian manuscript the first book is wanting, but it has no blank spaces like the Parisian one, and it is accompanied with a preface by the translator, containing an abstract of the work, and stating that the fifth book is imperfect. The translator mentions that the second book had been previously translated from Arabic into Latin by Amiratus Eugenius, a Sicilian, from the latest of two copies of which, the new translation was made. The following abstract of this interesting work is taken from Delambre's Analysis, and from the translator's abstract as communicated to us by Professor Rigaud.

Ptolemy. Born 70.

"The Optics of Ptolemy consists of five books. The *first* book is wanting, but from the recapitulation of it at the beginning of the second, it appears to have contained a dissertation on the relations between light and vision, founded on the idea that the visual rays issue from the eye. In the *second* book he shews that we see better with two eyes than with one, and that the object is not seen in the same place with one eye as with two. Vision, he says, is single, if the two axes of the pyramids of the visual rays are directed in the same manner on the object, but becomes double if the axes are not directed in a similar manner, and if the distance is a little less than the distance between the eyes. He next proceeds to find, geometrically, the circumstances which produce single or double images. He ascribes imperfection of sight in old men to a want of the visual virtue, which, like the other faculties, decays with the approach of age; and he states that those who have *concave* eyes see at a less distance than those who have not such eyes. Rapidity of motion, he asserts, confounds the colours on a wheel. If the colour is in the direction of a radius the wheel will appear entirely of this colour, and if different colours are at different distances from the centre, these will

---

[1] Euclidis *Optica et Catoptrica* nunquam antehac Græce edita. Eadem Latine reddita per Joannem Penam, Regium Mathematicum. His præposita est ejusdem Joannis Penæ de usu optices prefatio, ad illustrissimum principem Carolum Lotharingum Cardinalem. Parisiis, 1557.

[2] Dr. Smith is of opinion that this treatise was not written by Euclid the geometer; an opinion which he rests on the number of blunders which the author has committed. Smith's *Optics*, vol. ii. Rem. p. 16. § 93.

appear on the wheel as so many concentric circles differently coloured. When, after looking long at a coloured object, we direct the eye to another, we attribute to it the colour of the first.

"In the *third* book, which treats of reflexion from plane and concave mirrors, he shews, that in a plane mirror the object is seen in the perpendicular, drawn from the object to the plane of the mirror and continued behind it. He mentions that objects appear smaller towards the zenith and larger towards the horizon, because in the former case we see them in a position to which we are less accustomed.

"In concave mirrors the objects appear concave, and in convex ones they appear convex, and the image is seen at the point of intersection of the reflected ray, and the line drawn from the object to the centre of the sphere.

"The *fourth* book treats of concave and compound mirrors, and of the effects of two or more mirrors. In these mirrors an object may be reflected and rendered visible by all the parts of the mirror, or by three, or two, or even one point. The image may be either on the surface of the mirror, or before the surface, or behind the eye, or behind the mirror. When the image is behind the mirror, the distance of the object from the mirror is less than that of the image. When the image is between the eye and the mirror the distance of the object from the eye will be sometimes greater than the distance of the image from the mirror, and sometimes it will be equal to it, and sometimes less. When the object is between the mirror and the eye it will be seen in a part different from that where it really is; and if we give it a motion in one direction it will appear to move in the opposite direction.

"The *fifth* book is the most curious and valuable of the whole work. Ptolemy begins by explaining the experiment with the piece of money, which, when concealed behind the side of a vessel, becomes visible by filling it with water. The refraction of the visual ray in penetrating the water makes us see the piece of money out of its place, and in the prolongation of the primitive direction of the ray emitted from the eye. In order to measure this refraction at different angles, Ptolemy employs a circle divided into 360°, the inferior half of which is plunged in the water, so that the refracting surface covers one of the diameters of the circle. The centre of the circle is marked by a small coloured body, and a second similar body is fitted to one of the quadrants out of the water, and at a given distance from the vertical diameter; a third coloured body slides on the lower part, which is immersed in the water. This last body is then pushed with a rod till the eye placed on the body in the air sees all the three in a straight line. The two distances of the second and third body from the vertical diameter are thus measured on the graduated circle.

"In this manner Ptolemy obtained the results in the following table, which contains the angles of refraction from *air* to *water* from 10° up to 80° of incidence.

Angles of incidence.	Angles of refraction.	Ratio of the sines of the angles of incidence and refraction.
0°	0° 0′	
10	8 0	1 to 0·80143
20	15 30	1 — 0·78136
30	22 30	1 — 0·76537
40	28 0	1 — 0·73037
50	35 0	1 — 0·74875
60	40 30	1 — 0·76992
70	45 0[1]	1 — 0·75249
80	50 0	1 — 0·77786

The mean of these ratios is 0·76736, differing little from the correct one, viz. 0·7486; and it is interesting to remark, that at an incidence of 40° and 50, where the angle of refraction can be measured most accurately, the results of Ptolemy approach very near to the truth.

"In order to measure the angles of refraction from air into glass, Ptolemy adopted the ingenious idea of procuring a semi-cylinder of pure glass, and adjusting the diameter of it so as to coincide with the horizontal diameter of the graduated circle already described. By performing the very same experiments which he made with water, he found that there was no refraction at a perpendicular incidence; but that for every other position the angle in the air was always greater than the angle in the glass, and the refraction greater than in water. When the three bodies were placed in appearance in the same straight line they always remained there, whether the eye was placed above the glass or below it. The following are the refractions from *air* to *glass* which he obtained in this manner:—

Angles of incidence.	Angles of refraction.	Ratio of the sines of the angles of incidence and refraction.
0°	0° 0′	
10	7 0	0·70179
20	13 30	0·68255
30	20 30[2]	0·70041
40	25 0	0·65748
50	30 0	0·65270
60	34 30	0·65403
70	38 30	0·66247
80	42 0	0·67946

The mean of these ratios is 0·67386, whereas the true ratio is 0·64516; but at the angles of incidence of 40°, 50°, and 60°, the ratio is very near the true one.

When the semi-cylinder of glass was placed on the surface of water, Ptolemy observed that the refractions from water into glass were less than any he had observed, because the difference of density between *water* and *glass* was less than between *water* and *air*. The following were the results which he obtained:—

Angles of incidence.	Angles of refraction.	Ratio of the sines of the angles of incidence and refraction.
0°	0° 0′	
10	9 30	0·95044
20	18 30	0·92774
30	27 0	0·90778
40	35 0	0·89233
50	42 30	0·88192
60	49 30	0·87804
70	56 0	0·88422
80	62 0	0·89657

The mean of these ratios is 0·90, the true ratio being 0·8760, the index of refraction for water being 1.336, and that of glass 1·525; but at the angles of incidence of 50°, 60°, and 70°, the ratio is very near the true one.

Ptolemy now discusses the important subject of astronomical refraction, which he ascribes to the difference of density between ether and air. If the visual ray, he remarks, is stopped by an impenetrable body, it could not shew us a body which is hid behind the first; and if the second becomes visible, it can only be on account of the flexion of the visual ray. This flexion takes place at its passage into a medium of different density; and the possibility of this flexion, he asserts, may be proved by the following phenomena. By observations on the stars, it was found that the parallels drawn through the apparent place of those which rise or set, are those nearer the north pole than the paral-

[1] This is 45° 30′ in the Oxford manuscript.
[2] In the Oxford MS. this is 18° 30′. Professor Rigaud supposes the real number to have been 19° 30′.

History.

lels which pass through their apparent place when they are in the meridian; and the nearer the stars are to the horizon, the greater is the approach of their parallels to the pole. By observing a circumpolar star, Ptolemy found that it was nearer the pole in its lower passage across the meridian; but when it was near the zenith, its parallel became greater in appearance, whereas in the first case it became smaller. Hence it follows that refraction raises the stars towards the zenith. In order to explain the manner in which refractions operate, Ptolemy makes use of the same figure upon which Cassini has since founded his theory. He employs almost the same reasoning in order to determine the quantity of the refraction. He remarks, that the more a star is elevated, the less will be the difference between its true and its apparent place, and that this difference will be nothing in the zenith, because a perpendicular ray experiences no flexion. He demonstrates by a figure, that in every case the refraction carries the star towards the zenith; and he states that the height of the atmosphere is unknown, but that it must begin below the sphere of the moon. From this general account of the fifth book of the Optics of Ptolemy, it will be seen that he gives a theory of astronomical refractions much more complete than that of any astronomer before the time of Cassini.

These important results, which, without any other assistance, would have enabled the optician to trace the progress of the rays of light through lenses of all forms, were not applied as they might have been, to extend the boundaries of the science. Banished from Europe, optics, along with the other sciences, found shelter in Arabia; and after a period of a thousand years, it was destined to receive fresh accessions in that favoured country.

Alhazen. A.D. 1100.

Alhazen, who flourished about the end of the eleventh century, was the individual who gave this fresh impulse to optical science.[1] He establishes the opinion of Pythagoras, that vision is performed by rays which proceed from the object to the eye; and he states that vision is not completed till the ideas of external objects are conveyed by the optic nerves to the brain; and after a description of the eye and its parts, he assigns to each of them the function which it performs in vision. He maintains that we see objects singly with two eyes, because we must perceive only one image when it is formed on corresponding parts of the retina. The instrument employed by Alhazen for measuring the angle of refraction, is more complex than that used by Ptolemy, and his knowledge of the refraction of the atmosphere and of fluids, is obviously inferior to that of the Alexandrian philosopher. Alhazen ascribes to refraction the twinkling of the stars, and the contraction of the diameters and distances of the heavenly bodies; and it follows from his method of reasoning, that refraction elevated the stars towards the pole and not towards the zenith, as had been sagaciously ascertained by Ptolemy. Alhazen has described *seven* species of mirrors, and he was the first person who determined the focus of rays after reflexion, when the place of the object is known. He has treated largely of optical illusions, whether produced in direct or in refracted and reflected vision; and he ascribes the size of the horizontal moon to the apparent form of the concavity of the sky, which is imagined to be more remote in the horizon than any where else. Alhazen likewise observed that objects were magnified when held close to the plane wall of the larger segments of a glass sphere; and he has given rules, which are far from being correct, for determining the apparent size of objects when seen through such spheres.

Vitello. A.D. 1270.

The next cultivator of optics was Vitello, whose work was first published at Nuremberg in 1535.[2] He made a series of experiments on the angles of refraction of water and glass, which apparently exceeded those of Ptolemy in correctness, the mean ratio of the sines being nearer the truth, and the ratio for each angle of incidence coinciding more accurately with the mean ratio. The following are the results he obtained with *water*:—

Angles of incidence.	Angles of refraction.	Ratio of the sines.
0°	0° 0′	
10	7 45	0·77658
20	15 30	0·78135
30	22 30	0·76537
40	29 0	0·75423
50	35 0	0·74875
60	40 50	0·74992
70	45 30	0·75904
80	50 6	0·77787

The mean of these ratios is 0·76414, whereas that obtained by Ptolemy was 0·76736, and the true ratio (the index of refraction being 1·3358), 0·7486. The results for 30° and 60° are exactly the same as Ptolemy's.

The following were the measures obtained by Vitello for *glass*:—

Angles of incidence.	Angles of refraction.	Ratio of the sines.
0°	0° 0′	
10	7 0	0·70179
20	13 30	0·68255
30	19 30	0·66761
40	25 0	0·65748
50	30 0	0·65270
60	34 30	0·65403
70	38 30	0·66247
80	42 0	0·67946

The mean of these ratios is 0·66976, whereas that obtained by Ptolemy is 0·68736, and the true ratio 0·64516.

In comparing this last table with the similar one given by Ptolemy, we cannot fail to be struck with their entire similarity, with the single exception of the angle of refraction at 30° of incidence, which Vitello makes 19° 30′, and Ptolemy, in the Paris copy, 20° 30′. Now, in the Oxford manuscript, the numbers are 18° 30′; and Professor Rigaud conjectures that the real number has been 19° 30′, the same as Vitello's. Hence we cannot on any just grounds regard the measures of refraction given by the Polish philosopher as any thing else than those of Ptolemy, from whom he must have borrowed them.

By comparing the two tables for water, we are inclined to make the same unfavourable supposition. The refraction for 20°, 30°, and 50° of incidence are exactly the same in both; and Vitello's measure for 70°, viz. 45° 30′, is the same as Ptolemy's in the Oxford manuscript.

But this opinion is converted into certainty when we examine Vitello's table of the refractions from water into glass, in which all the measures are *identically* the same with those of Ptolemy.

In the course of his experiments, Vitello was led to observe that whenever light was reflected or refracted by transparent bodies, a certain portion of it was lost, but he does not estimate the quantity, contenting himself with the observation that bodies always appear less luminous when seen by refracted and reflected light. In treating of the cause of the rainbow, he shews that refraction is as neces-

[1] Montucla has very incorrectly charged Alhazen with borrowing the greater part of his optics from Ptolemy. Delambre has refuted this opinion, and rendered it probable that the Arabian philosopher never saw the work of Ptolemy. What assistance he obtained from his predecessors who flourished after Ptolemy cannot now be ascertained. See *Connaissance des Tems* for 1816.

[2] This work has been very erroneously regarded as little more than a translation of Alhazen's treatise.

History.

sary to its production as reflexion, but he of course does not ascribe the colours to refraction, regarding it merely as a means of giving strength or condensation to the solar rays. He imitated the colours of the rainbow, (which, like Seneca, he considers as having their origin in a mixture of the sun's rays with the blackness of the cloud), by placing a white piece of paper beneath a circular vessel of glass containing water; but he says that they are not the same colours with those of the rainbow, because they are not in the same number, and do not reach the eye after reflexion. He shews that in those countries where the meridian altitude of the sun exceeds the semi-diameter of the rainbow, a rainbow cannot be seen at noon. His observations on the foci of glass spheres, on the twinkling of the stars, and on other optical phenomena, are of no value, and rather tend to confirm the severe censures which Baptista Porta has pronounced upon his scientific character.

Passing over archbishop Peckham's treatise on optics, entitled *Perspectiva Communis*, as containing nothing either new or important, we come to consider the claims of Roger Bacon to the invention of the microscope and the telescope. In his *Opus Majus*, which embraces his *Perspectiva* and *Specula Mathematica*, he has given an account of his speculations and inventions in optics. Dr. Plott, Dr. Friend, Dr. Henry, Wood, Muschenbroek, Jebb, and William and Samuel Molyneux have agreed in regarding Bacon as the inventor of the telescope, while Dr. Smith of Cambridge is of opinion that he wrote only *hypothetically*, and had never made any experiments with real lenses. As this is not the place to discuss this subject in a critical manner,[1] we shall content ourselves with giving a single extract respecting the telescope and microscope.

Roger Bacon. Born 1214.

"Greater things than these may be performed by refracted vision. For it is easy to understand by the causes above mentioned, that the greatest things may appear exceeding small, and on the contrary; also that the most remote objects may appear just at hand, and on the contrary. For we can give such figures to transparent bodies, and dispose them in such order with respect to the eye and the objects, that the rays shall be refracted and bent towards any place we please; so that we shall see the object near at hand, or at a distance, under any angle we please. And thus from an incredible distance we may read the smallest letters, and may number the smallest particles of dust and sand, by reason of the greatness of the angle under which we may see them; and on the contrary, we may not be able to see the greatest bodies just by us, by reason of the smallness of the angles under which they may appear; for distance does not affect this kind of vision, excepting by accident, but the quantity of the angle. And thus a boy may appear to be a giant, and a man as big as a mountain, forasmuch as we may see the man under as great an angle as the mountain, and as near as we please; and thus a small army may appear a very great one, and, though very far off, yet very near us, and on the contrary. Thus also the sun, moon, and stars may be made to descend hither in appearance, and to appear over the heads of our enemies; and many things of the like sort, which would astonish unskilful persons."

Whether these remarks were the result of speculation or of actual experiment, it is not easy at this distance of time to determine; but in opposition to the opinion of Dr. Smith, we may adduce a passage from Recorde's *Pathway to Knowledge*, printed in 1551, in which he distinctly speaks of a glasse used by friar Bacon. "Great talke there is of a glasse he made at Oxford, in which men might see things that weare don, and that was iudged to be don by power of euill spirites. But *I know* the reason of it to be good and natural, and to be arright by geometry (with perspective as a part of it), and to stand as well with reason as to see your face in a common glass."

Invention of Spectacles.

On the authority of various passages in the writings of friar Bacon, Mr. Molyneux is of opinion that he was acquainted with the use of spectacles, and when Bacon says that "this instrument (a plano-convex glass, or large segment of a sphere), is useful to old men, and to those that have weak eyes; for they may see the smallest letters sufficiently magnified," we are at least entitled to conclude that the particular way of assisting decayed sight which he describes was known to him, though he may not have used his segment of a glass sphere in looking at objects separated by an interval from its plane side. But whether spectacles were in use or not in Bacon's time, it is quite certain that they were known and used about the time of his death, which happened in 1292. Alexander de Spina, a native of Pisa, who died in that city in 1313, having seen a pair of spectacles made by some other person, who was unwilling to communicate the secret of their construction, got a pair made for himself, and found them so useful, that he cheerfully made the invention public. M. Spoon,[2] to whom we are indebted for this fact, fixes the date of the invention between 1280 and 1311. Signior Redi, from whom Spoon quotes the preceding fact, states that he possesses a manuscript written in 1299, *Di Governo della Familia de Scandro di Pissozzo*, in which the author says, "I find myself so pressed by age, that I can neither read nor write without those glasses they call spectacles, lately invented, to the great advantage of poor old men, when their sight grows weak." It is stated also in the Italian Dictionary *Della Crusca*, under the head of *Occhiale* or *Spectacles*, that friar Jordan de Rivalto, who died at Pisa in 1311, tells his audience, in one of his sermons, which were published in 1305, "that it is not twenty years since the art of making spectacles was found out, and is indeed one of the best and most necessary inventions in the world." Bernard Gordon, too, a celebrated physician of Montpellier, in his *Lilium Medicinæ*, published about 1305, recommends an eye salve as capable of making the patient read the smallest letters without spectacles; and Muschenbroek informs us that it is inscribed on the tomb of Salvinus Armatus, a Florentine nobleman, who died in 1317, that he was the inventor of spectacles.

Leonard Digges. Died 1574.

Before we quit the period of Friar Bacon we must notice a claim to the invention of the telescope which has been made in favour of Leonard Digges, an Englishman, because this claim, whatever be its amount, supports undeniably the prior claim of Bacon. The claim of Digges is founded on passages in his *Pantometria* and *Stratiotikos*. The first of these works appeared at London in 1571, and a second edition of it, edited by his son Thomas Digges, Esq., was published in 1591. The *Stratiotikos* was published in 1579 and also in 1590. In the preface to the second edition of the *Pantometria*, Thomas Digges remarks: "My father, by his continuell painfull practices, assisted by demonstrations mathematical, was able, and sundrie times hath, by proportionall glasses, duely situate in conuenient angles, not onely discouered things farre off, read letters, numbred peeces of money, with the verye coyne and superscription thereof, cast by some of his freends of purpose upon downes in the open fields, but also seuen miles off declared what hath beene doone in priuate places."

In the twenty-first chapter of the first book, Leonard Digges himself says, "But marvellous are the conclusions that may be performed by glasses (mirrors) concave and convex, of circular and parabolic forms, using for multiplications of

[1] We must refer our readers to a series of able anonymous letters upon this subject, published in the *Philosophical Magazine*, vols. 18, 19.

History.

beams, sometimes the aid of glasses transposed, which, by practice, should unite or dissipate the images or figures presented by the reflection of others. By these kind of glasses, or rather frames of them placed in due angles, yee may not only set out the proportion of an whole region, yea, represent before your eye the lively image of every house, village, &c., and that in as little or great space or plan as ye will presente; but also augment or dilate any parcell thereof, so that, whereas, at the first appearance a whole toun shall present itself so small and compact together that ye shall not discover any difference of streets, yee may, by application of glasses in due proportion, cause any peculiar house or room thereof dilate and shew itself in as ample form as the whole touns at first appeared, so that yee shall discern any trifle, or read any letter lying there open, especially if the sun beams may come into it, as plainly as if you were corporeally pressent, although it be distant from you as far as eye can discrie. But of these conclusions I mind not here more to introduce, having at large, in a volume by itself, opened the miraculous effects of perspective glasses."

Now it is a curious fact that Thomas Digges expressly says that his father's knowledge of optics "partly grew by the aid he had by one old written book of Bakon's Experiments, that by strange aduenture, or rather destinie, came to his hands."

In support of the opinion that the telescope was known in England more than forty years before 1609 or 1610, when it was supposed to have been invented in Holland, we may quote a passage or two from the celebrated John Dee's mathematical preface to Euclid, written at Matloke on the 9th of February 1570, the year in which it was published. "Is it not," says he, "greatly against the sovereignty of man's nature to be so overshot and abused with things before his eyes? things far off to seem neer, and neer to seem far off; small things to seem great and great to seem small; one man to seem an army, or a man to be constantly afraid of his own shadow; yea, so much to fear, that if you, being alone, near a certain glasse,[1] and profer with dagger or sword to foyne at the glasse, you shall suddenly be moved to give back by reason of an image appearing in the air between you and the glass, with like hand, sword, or dagger, and with like quickness foyning at your eye, likewise as you do at the glasse." He then mentions that such a glass was in the possession of a gentleman famous and honourable for his good service done to his country. Dee likewise speaks of having seen once or twice in company with Orontius at St. Denis in 1551; "The lively image of another man in the air aloft, walking to and fro or standing still;" but the most remarkable passage is that in which he speaks of the means of ascertaining the numbers of an enemy's army; "The herald, pursuivant, sergiant royall, captain, or whosoever is careful to come near the truth herein; besides the judgment of his expert eye, his skill of ordering tacticaly, the help of his geometrical instrument; ring or staffe astronomical, commodiously framed for carriage and use. *He may wonderfully help himself by perspective glasses*, in which I trust our posterity will prove more skilful and expert, and to greater purposes than in these days can be credited to be possible."

When polite learning began to revive in Europe some of the more abstract sciences began to be cultivated with success. Maurolycus, a teacher of mathematics at Messina, was particularly distinguished by his optical researches, of which he published an account in his *Theoremata de Lumine et Umbra* and his *Diaphanorum Partes, seu libri tres.* In the first of these works, which was completed in 1525, but not published till 1575, Maurolycus treats of the measure of light, or the illumination of bodies, and he particularly explained the curious phenomenon which had been observed since the time of Aristotle, that when the sun shone through an aperture of any form, the figure of the aperture always appeared round, except when the sun was eclipsed, when it had the appearance of a crescent. He shews that each point of the aperture is the apex of two opposite cones of rays, one of which has the sun for its base, while the other, when cut by a plane at right angles to its axis, will produce a luminous circle, whose diameter will be proportional to the distance of the plane from the aperture. "Consequently if these images be taken at a considerable distance from the aperture, and therefore be pretty large when the aperture itself is small; since the whole image consists of a number of images, all of which are circular, the image of the sun formed by the aperture, of whatever form it be, must be circular also; and it will approach the nearer to a perfect circle the smaller is the aperture and the more distant the image." It may be easily shewn, indeed, that a small aperture acts like a lens in forming an inverted picture of all external objects in a dark chamber, and that then pictures become more distinct in their outline as the aperture becomes smaller. Hence the sun's image is round, or a crescent, according as the sun's disc is entire or eclipsed. In studying the phenomena of vision Maurolycus was very successful. He shews that the crystalline humour is a lens which collects the rays which enter the eye and converges them to foci on the retina; but he does not seem to have found that these foci depict an exact image or picture of the object upon the retina. Limited, however, as this discovery was, it enabled him to ascertain the cause of *long* and *short-sightedness*, the pencils in the former case coming to a focus before they entered the retina, and in the latter at points beyond the retina. Hence, as in both these cases, vision is indistinct either from a too early or a too late convergence of the rays, he concluded that concave glasses of suitable focus would relieve the short-sighted person, and convex glasses the long-sighted person.

Maurolycus. A.D. 1525.

The subject of the rainbow also occupied Maurolycus's attention. He found the diameter of the outer bow 42°, and that of the inner from 53° to 56°; but according to the theory which he adopted, namely that part of the sun's rays were partly reflected from the exterior of the drop, while the rest entered the drop and circulated within it by reflexion along the sides of an octagon; the diameters of the bow should have been 45° and 56°. Maurolycus supposed the colours of the rainbow to be *four*, namely, *orange, (crocus), green, blue*, and *purple*. Taking his *crocus* to be red, his enumeration in leaving out the yellow, as Dr. Wollaston did more recently, shew much accuracy of observation.[2] Maurolycus attempted to discover the law of refraction but without success. He supposed that the angle of refraction was always five-eighths of the angle of incidence, which is a tolerably correct estimate in the case of glass, but quite erroneous for bodies of low and high refractive powers.

Maurolycus may be considered as the first discoverer of the aberration of figure, in so far as he observed that the rays which were incident at a distance from the axis of a transparent sphere, had their focus nearer the sphere than those which were incident nearer the axis. This happy observation was the result of his having noticed the caustic curves formed by such spheres, which he justly described as arising from the continued intersections of the refracted rays.

While the Sicilian philosopher was making new and important discoveries a celebrated Neapolitan, Joannes Baptista Porta, was endeavouring to promote the interests of science, as an ardent collector of its stores, as well as an original inquirer into its mysteries. He established an Academy of Sciences

[1] By a glass, he means "any thing from which a beam reboundeth."

[2] The yellow which is in the sun's direct rays is observed when the sun's rays are reflected from the sky or from clouds.

History.

which held its sittings in his own house, and which numbered among its members all the *virtuosi* in Naples. Each member was bound to contribute to the common stock something not commonly known, and in this way he obtained the materials for his *Magia Naturalis* which appeared in the year 1560,[1] when he was only about fifteen years of age. This work was speedily translated into French, Hebrew, Spanish, and Arabic, and went through numerous editions in different parts of Europe. The Papal court viewed with jealousy the proceedings of a society which devoted so much energy to the spread of knowledge, and, though Baptista Porta was a Roman Catholic, the meetings of the academy were prohibited by the ecclesiastical power. Although Baptista Porta was well acquainted with the writings of his predecessors, yet the principal invention recorded in his Natural Magic is that of the camera obscura, which he seems to have brought to great perfection. He remarks, in the 17th chapter of this work, that if a small aperture is made in the shutter of a dark room, distinct images of all external objects will be depicted on the opposite wall in their true colours; and he further adds that if a convex lens be fixed in the opening, so that the images are received on a surface at the distance of its focal length, the pictures will be rendered so much more distinct that the features of a person standing on the outside of the window may be readily recognised in his inverted image. Various attempts seem to have been made to obtain an erect image of objects in the camera obscura, but the contrivances for this purpose had the effect, as Baptista Porta assures us, of making the pictures so obscure that there was no pleasure in viewing them. He observes, however, that the image may be best rendered erect by receiving it "upon a concave mirror properly adapted to the convex lens and held at a great distance from the hole." The effect of this expedient, he says, cannot be sufficiently admired. Baptista Porta applied his instrument to the representation of eclipses of the sun, and of hunting scenes, battles, and other events produced by moveable pictures and drawings. In this way he magnified small objects and drawings, and produced the effects of the magic lantern by the light of the sun in place of that of a lamp. He considered the eye as a camera obscura, the pupil as the hole in the window contracting and dilating with different lights, and the crystalline lens as the principal organ of vision, though he seems to have regarded it not as his convex lens but as the tablet on which the images of external objects were formed, the cornea being, no doubt, in his estimation, the part of the eye which formed the picture. Baptista Porta was doubtless acquainted with what may be called the simplest form of the refracting telescope, namely, that in which a convex lens is the object-glass, and the eye placed six inches behind its focus, the eye-glass. He found that when his eye was thus placed behind a convex lens, he could read a letter which he could not read with his naked eye. His lens must have exceeded in focal length, the distance at which his eye saw distinctly, for the magnifying power of such a telescope is equal to the focal length of the object-glass divided by that distance.

In another place Porta, after mentioning the effects produced by a concave and a convex lens separately, remarks, "that if you knew how to combine one of each sort rightly, you would see both far and near objects larger and more clearly." "If Porta," says Mr. Drinkwater Bethune, in his admirable life of Galileo, "had stopped here, he might more securely have enjoyed the reputation of the invention, but he then professes to describe the construction of his instrument, which has no relation whatever to his previous remarks." "I shall now endeavour to shew in what manner we may contrive to recognise our friends at the distance of several miles, and how those of weak sight may read the most minute letters from a distance. It is an invention of great utility, and grounded on optical principles, nor is it at all difficult of execution; but it must be so divulged as not to be understood by the vulgar, and yet be clear to the sharp-sighted." The description which follows, seems far enough removed from the apprehended danger of being too clear; and indeed every writer who has hitherto quoted it, has merely given the passage in its original Latin, apparently despairing of an intelligible translation. With some alterations in the punctuation, which appear necessary to bring it into any grammatical construction, it may be supposed to bear something like the following meaning:—"Let a view be contrived in the centre of a mirror, where it is most effective. All the solar rays are exceedingly dispersed, and do not in the least come together (in the true centre); but there is a concourse of all the rays in the central part of the said mirror, half way towards the other centre, where the cross diameters meet. This view is contrived in the following manner: A concave cylindrical mirror placed directly in front, but with its axis inclined, must be adapted to the focus; and let obtuse angled, or right angled triangles be cut out with two cross lines on each side drawn from the centre, and a glass (*specillum)* will be completely fit for the purposes we mentioned." If it were not for the word *specillum*, which, in the passage immediately preceding this, Porta contrasts with *speculum*, and which he afterwards explains to mean a glass lens, it would be very clear that the foregoing passage, supposing it to have any meaning, must be referred to a reflecting telescope; and it is a little singular, that whilst this obscure passage has attracted universal attention, no one, so far as we are aware, has taken any notice of the following unequivocal description of the principal part of Newton's construction of the same instrument. It is in the fifth chapter of the seventeenth book, where Porta explains by what device exceedingly minute letters may be read without difficulty. "Place a concave mirror so that the back of it may lie against your breast; opposite to it and within the burning point, place the writing; put a plane mirror behind it, that may be under your eyes. Then the images of the letters which are in the concave mirror, and which the concave has magnified, will be reflected in the plane mirror, so that you may read without difficulty."[2]

On these grounds Porta claimed for himself the invention of the telescope; and his death which took place in 1615, at the age of eighty, is said to have been hastened by the exhaustion of writing a work on that instrument.

At a more advanced age, Baptista Porta composed another work entitled, *De Refractione Optices parte, libri novem*, which appeared in 1593, but contains nothing that is deserving of particular notice.

The subject of the rainbow, which had hitherto been a *questio vexata* among philosophers, now began to excite notice, as much from the absurdity of the theories which were advanced to explain it, as from the native interest of the subject. Clichtoveus, whom Dr. Priestley supposes to be the person who distinguished himself by his opposition to Luther, had maintained that the second rainbow was a reflected image of the first, not only from the faintness of its light, but from the inversion of its colours; an opinion which our celebrated countryman, Dr. Gilbert has justly ridiculed, alleging, that the whole form of the bow ought to be inverted as well as its colours, and that it ought to have its convex side downwards.

Clichtoveus. Died 1543.

A more correct theory of the rainbow was about this time proposed by J. Fleschier of Breslau, in his treatise entitled, *De Iridibus doctrina Aristotelis et Vitellionis*, which was published in 1571. He supposes the rays to suffer two refractions, one on entering, and the other on emerging

Fleschier. A.D. 157

[1] A second and greatly enlarged edition was published about thirty years afterwards. [2] *Life of Galileo*, Libr. Useful Knowledge, p. 21.

History.

from the drop, but after one ray had thus been separated into a coloured beam by these refractions, he supposed that this beam was reflected to the eye from another drop.

De Dominis. Born 1561. Died 1662.

These views, imperfect as they are, paved the way for the true theory of the rainbow. Antonio de Dominis, archbishop of Spalatro, first broached this theory in his treatise *De Radiis Visus et Lucis*, which was published in 1611. He justly asserts that two refractions in a drop of water, and one intermediate reflection, were sufficient to bring back to the eye of the spectator the rays of light by which the bow was formed. An experiment with a globe of glass enclosing water, either suggested to him or confirmed this opinion. In following out this experiment, however, our author committed several mistakes. He explained the exterior bow by the same number of refractions and one reflexion, but he supposed that the rays which formed it were returned to the eye by a part of the drop lower than that which transmitted the red of the interior bow. In addition to this mistake, he supposed that the rays which went to form one of the bows, came from the upper part, and that which went to form the other bow from the under part of the sun's disc. Notwithstanding these mistakes, De Dominis is entitled to be regarded as the true discoverer of the cause of the primary rainbow.

The treatise containing these discoveries was not published till after the use of the telescope by Galileo, but Bartolo, who published it, informs us in the preface, to use the words of the author of the *Life of Galileo*, "that the manuscripts was communicated to him from a collection of papers written twenty years before, on his enquiring the archbishop's opinions with respect to the newly discovered instrument, and that he got leave to publish it, 'with the addition of one or two chapters.' The treatise contains a complete description of a telescope, which, however, is proposed merely to be an improvement on spectacles; and if the author's intention had been to interpolate an after-written account in order to secure to himself the undeserved honour of the invention, it seems improbable that he would have suffered an acknowledgment of additions, previous to publication, to be inserted in the preface. Besides, the whole tone of the work is that of a candid and truth-seeking philosopher, very far indeed, removed from being, as Montucla calls him, conspicuous for ignorance even among the ignorant men of his age. He gives a drawing of a convex and concave lens, and traces the passage of the rays through them; to which he subjoins, that he has not satisfied himself with any determination of the precise distance to which the glasses should be separated according to their convexity and concavity, but recommends the proper distance to be found by actual experiment, and tells us that the effect of the instrument will be to prevent the confusion arising from the interference of the direct and refracted rays, and to magnify the object by increasing the visible angle under which it is viewed."[1]

From the great liberality of his sentiments, and his conversion to the protestant faith, this eminent ecclesiastic was obliged to leave Italy, and to take refuge in London, in 1616, where he lived some years. Having been induced to return to Italy, his imprudence exposed him to new persecutions, and having been imprisoned by Urban VIII. he died of poison in the prison of the Inquisition. Sentence was passed upon him after his death, and his body, with all his books and papers were publicly burnt in the Campo de Fero, in the year 1624.

Invention of the telescope.

We now approach the time when the telescope was unquestionably invented. We have no doubt that this invaluable instrument was invented by Roger Bacon or Baptista Porta, in the form of an experiment, though it perhaps had not in their hands assumed the maturity of an instrument made for sale, and applied to useful purposes both terrestrial and celestial. If a telescope is an instrument by means of which things at a distance can be seen better than by the naked eye, then Baptista Porta's concave lens with his eye looking at the image which it formed, and reading a letter too remote to be otherwise legible, was a real telescope; but if we give the name to a tube having a convex object glass at one end, and a convex or a concave lens at the other, placed at the distance of the sum or the difference of their focal lengths, then we have no distinct evidence that such an instrument was used before the beginning of the seventeenth century.

In his *Treatise on Dioptrics*, Descartes has ascribed the invention of the telescope to James Metius, a citizen of Alkmaer in Holland; but Huygens in mentioning this claim[2] says, that "*to his certain knowledge* telescopes were made before this, at Middleburg in Zealand, about the year 1609, either by John Lippersheim, whom Sirturus mentions, or by Zacharias (Jansen), whom Borellus makes the first inventor of them in his book *de Vero Telescopii inventore*. The telescope which they made did not exceed a foot and a half long. But much earlier than both, Joannes Baptista Porta a Neapolitan, had delivered the rudiments of this art in his book on dioptrics and natural magic, published fifteen years before telescopes appeared in our Belgium. In these books he speaks of his *specilla* as shewing things placed at a distance as if they were nigh, and also of the construction of concave and convex lenses. But that he made no great progress in this art is hence evident, that in all that time it did not become famous; and that he did not discover any of those things in the heavens that were observed afterwards. And this shews that his invention was not owing to his skill, but to some accidental experiments. For though he had some degree of knowledge in mathematicks, yet he did not understand those fundamental principles and abstruse theorems in dioptricks, that are necessary to invent a telescope by reason; and by much less did those illiterate mechanicks that I mentioned before. But no wonder that good luck and casual experiments should produce this effect; after spectacles and concave glasses, for defective eyes of both sorts, had been commonly used for above three hundred years, it is rather surprizing that so obvious a thing should be so long unknown."

In this passage Huygens leaves the claims of his two Dutch friends on the same level; but though Borellus adopts the conclusion that Jansen was the inventor, yet it has been ingeniously suggested, that Jansen's claim as the inventor of the microscope, has been mixed up with the invention of the telescope, on the evidence adduced by Borellus. On this hypothesis Lippersheim is supposed to have invented the telescope by accident in 1609, and that Jansen possessing an instrument so like it, had been able, after hearing of Lippersheim's contrivance, to make a similar instrument without having seen the telescope of his rival.[3]

Much light has recently been thrown on the history of the telescope by Professor Moll, who has discussed the claims of the various competitors with much sagacity and fairness. It appears from the official acts and journals of the States General of Holland, still existing among the archives at the Hague, that on the 2d of October 1608 that body took into consideration a petition from Hans (John) Lippershey, a native of Wesell, and spectacle maker at Middleburg, praying, that an instrument which he had invented for seeing at a distance, might be rewarded, either by granting an exclusive privilege of making it for thirty years, or an annual pension to enable him to make these instruments for Holland alone. It was resolved, that a commit-

[1] *Life of Galileo*, Libr. Useful Knowledge, p. 22. [2] *Dioptrics*, p. 163–4. [3] *Life of Galileo*, Libr. Useful Knowledge, p. 24.

History.

tee should communicate with the petitioner, and enquire if he could not so improve the instrument *so as to enable one to look through it with both eyes.* Lippershey offered to make three telescopes of *rock crystal* for *one thousand florins* each, (about L.83 each) but the committee was instructed to get him to moderate his charge, and promise never to transmit his invention to any body. On the 6th of October a bargain was made that Lippershey should construct one instrument of rock crystal for the State, at the price of 900 florins, (L.75) 300 florins to be paid down, and 600 when the telescope was completed and approved of. On the 16th December the committee report, "that they examined the instrument invented by Lippershey to see at a distance *with two eyes*, and that they approved of it." But, in reference to the exclusive privilege, they "resolved that, whereas it appears *that many other persons have a knowledge of this new invention* to see at a distance, it is expedient to refuse the prayer of the petitioner for an exclusive privilege, but that he will be commanded to make, within a certain time, two other instruments of his invention for seeing with two eyes, at the same price." These two new instruments were delivered before the 13th February 1609.

While these transactions were going on, Jacob Adriaansz, sometimes called Metius of Alkmaer petitioned the States-General on the 17th of October 1608, for an exclusive privilege for a similar instrument. He was the third son of Adriaan Anthonisz, or Metius, who discovered the approximate ratio of the diameter of a circle to its circumference. His petition still exists among the manuscripts of Huygens, in the library at Leyden. He alleges, that he began his researches as far back as 1606; that the invention was accidental, and when he was making other experiments; and that, in 1608, when he sent in his petition, his instrument was made of bad materials. He at the same time readily admits, that a spectacle maker of Middleburg had offered before him a similar instrument to the States, which had been tried by Prince Maurice, and other persons.

With regard to the claims of Zacharias Jansen, or rather Tansz or Zansz, they cannot be supported by any evidence, and there is reason to believe, as we shall afterwards see, that his invention of the microscope was mistaken for the invention of the telescope[1] The following is Professor Moll's summary of the facts which he has established by authentic documents.

"That on the 21st of October 1608, John, or Hans Lippershey, a native of Wezel, a spectacle maker of Middleburg, in Zeeland, was actually in possession of the invention of telescopes.

"That, on the 17th of October, of the same year 1608, Jacob Adriaansz, sometimes called Metius of Alkmaer in Holland, also was in possession of the art of making telescopes, and that he actually made those instruments; but that either from disgust or some other reason, he afterwards concealed his invention, and thus actually gave up every claim attached to the honour of it.

"That there is little reason to believe that either Hans, or his son Zacharias Zansz, were also inventors of the telescope; but there is every probability that this Hans, or John, or his son Zacharias Zansz, invented a compound microscope about 1590.

"That this Lippershey used rock or mountain crystal in the construction of telescopes, and that he is the inventor of the Binoculus."

Galileo's construction of the telescope. A.D.1609.

When Galileo was at Venice in 1609, he heard rumours that an instrument which represented distant objects as if they were near, had been invented by a Dutch spectacle maker. This rumour was confirmed by a letter which he received from James Badorere at Paris, and Galileo, who asserts that he had never seen one of the instruments, set himself to discover the principle of their construction, and to make one for his own use. It has become a question, though one of no interest, and affecting the veracity more than the reputation of Galileo, whether the Italian philosopher had actually seen one of the new instruments. We cannot hesitate for a moment in believing Galileo's assertion; and even if we confide in the statement made by Fucarius, that he had himself seen one of the Dutch telescopes, which at that time had been brought to Venice, it by no means follows that Galileo saw it.[2] It is quite certain, indeed, that previous to the 31st August 1609, one of the new perspective glasses had been sent from Flanders to the Cardinal Borghese,[3] and Lorenzo Pignoria, on the authority of whose letter of the above date this fact rests,[4] adds, "we have seen *some* here, and truly they succeed well."

The following is Galileo's account of the matter, from a letter which he wrote in March 1610: "It is about ten months ago that it came to our ears, that a glass had been worked by a Belgian, by the help of which, visible objects, though at a great distance from the eye of the observer, may be seen distinctly. (In the Italian of the Saggiatore it is added, *ne pia aggiunto, no more was added, or this was all.)* And some experiments were related of the admirable effects of this instrument, which some believed, and others not. A few days afterwards the same was confirmed by letters of a noble Frenchman, Jacob de Badorere, from Paris; all which occasioned me to apply myself wholly to enquire into the cause of this, and to think on the means by which the invention of a similar instrument might be brought about; in which I succeeded in a short time, assisted by the doctrine of refraction: and I first procured a leaden tube, (an organ pipe) at the end of which I adapted spectacle glasses, both plane on one side, the one convex on the other side, the second concave. Bringing the eye near the concave glass, I saw the objects large, and near enough: they appeared three times nearer, and nine times larger, than if seen with the naked eye.

"Afterwards I made another instrument, which made objects appear sixty times larger.

"Finally, sparing neither industry nor expence, I succeeded so far as to make an instrument of such excellence, as to make the objects seen through it appear a thousand times larger, and more than thirty times nearer, than if seen with the natural power of the eye."[5]

Galileo's first telescope must have been made in May or June 1610. Viviani[6] says, that it was in April or May 1609, that the rumour of the invention of the telescope reached Venice, when Galileo was there, and that, with this information only, Galileo returned to Padua and succeeded in finding out the principle in the following night.

The new instrument long went by the names of Galileo's *tube*, the *perspective*, and the *double eye-glass*, the

History.

more appropriate names of telescope and microscope having been afterwards given to these instruments by Demisiano.

Telescopes in England, A.D. 1609. Harriot.

Telescopes were early and eagerly imported into England, and known by the name of *trunks* and *cylinders*; and so soon as July 1609, we find that our countryman Harriot was directing them to the lunar disc, and had begun two full drawings of that luminary, which he afterwards completed.[1] Harriot's earliest observations on Jupiter's satellites were made on the 1st October 1610, nine months after their discovery by Galileo. The earliest telescope in England must therefore have been obtained from Holland; and in a letter from Sir William Lower to Harriot, dated *the longest day of* 1610, from Traventi in Caermarthenshire, he says, "we are here so on fire with these things, that I must render my request and your promise, to send more of all sorts of these cylinders. My man shall deliver you monie for anie charge requisite, and contente your man for his paines and skill. Send me so many as you think needful unto these observations: in requital I will send you store of observations. Send me also one of Galileus bookes, if anie yet be come over, if you can get them." In a letter dated July 6, 1610, Sir Christopher Heyden writes to his friend Camden, "I have read Galileus, and to be short, do concur with him in opinion, for his reasons are demonstrative; and of my own experience with one of our ordinary trunks, I have told eleven stars in the Pleiades, whereas no age ever remembers above seven, and one of these, as Virgil testifieth, not always to be seen."[2] From this and other facts, Professor Rigaud infers "that it is perfectly clear that Harriot and his friend had been in the habit of using telescopes before the discoveries of Galileo were known to them; and it appears likewise that in 1610,[3] they were manufactured in England." The magnifying power of some of the telescopes used by Harriot were $\frac{6}{1}$, $\frac{10}{1}$, $\frac{11}{1}$, $\frac{15}{1}$, $\frac{32}{1}$, $\frac{50}{1}$. In a letter from Sir William Lower to Harriot, dated Traventi, 6th July 1610, he says, "I have received the perspective cylinder that you promised me, and am sorrie that my man gave you not more warning, that I might have had also the two or three more that you mentioned to chuse for me. Henceforward he shall have orders to attend you better, and to defray the charge of this an others, for he confesseth to me that he forgot to pay the worke man.

"According as you wished, I have observed the moone in all his changes. In the new I discover manifestlie the earthshine a little before the dichotomie; that spot which represents unto me the man in the moone (but without a head) is first to be seene. A little after, neare the brimme of the gibbous parts, towards the upper corner, appeare luminous parts like starres, much brighter than the rest; and the whole brimme along lookes like unto the description of coasts in the Dutch bookes of voyages. In the full she appears like a tarte that my cooke made me the last weeke. Here a vaine of bright stuffe, and there of darke, and so confusedlie al over. I must confesse I can see none of this without my cylinder; yet an ingenious younge man that accompanies me here often, and loves you and these studies much, sees manie of these things, even without the helpe of the instrument, but with it sees them most plainlie, I mean the young Mr. Protheroe."

Astronomical telescope invented by Kepler, A.D. 1611.

It is highly probable that the first Dutch telescopes had their eye-glass concave, like Galileo's, though this supposition is opposed by the traditional story of a large and inverted image of a weathercock having been seen through the earliest of them, in which case the eye-glass must have been convex. Even so late as the period when Descartes published his *Dioptrics*, which was in 1637, no other telescope but a Galilean one had been described, excepting in Kepler's *Dioptrica*, which appeared at Frankfort in 1611. In his 86th proposition he explains the theory of the telescope, and has shewn how an instrument which produces the same effects might be made, by substituting for the usual concave eye-glass *one or more convex* eye-glasses. Kepler, however, does not seem to have constructed such a telescope, and father Scheiner[4] seems to have been the first person who embodied the plan in an actual instrument, which has ever since been known by the name of the *astronomical telescope*, in consequence of the inversion of the images not being disagreeable in astronomical observations.

Inventi[on] of the [mi]croscope. Janse[n].

The real inventor of the compound microscope is as little known as the inventor of the telescope. It would be in vain to inquire into the history of the single microscope, for the magnifying power of globes was known to the ancients; and no individual ambition or national partiality has endeavoured to assign the honour of inventing it to any person whatever. We agree with Professor Moll, that Zacharias Zansz, or Jansen, has the best claims to be considered as the inventor and constructor of the compound microscope. He seems to have made one so early as 1590, and to have presented one to the Archduke Albert of Austria, who gave it to Cornelius Drebell, who lived, as mathematician to the king, at the court of our James the First. William Boreel, the envoy to England from the States of Holland, saw in England, in 1619, and in the hands of Cornelius Drebell, the very microscope which Tansz had given to the archduke. This account of its history was given by Drebell himself. The microscope in question was eighteen inches long, consisting of a tube of gilt copper two inches in diameter, supported by two sculptured dolphins, resting on a base of ebony, upon which the objects were placed.

Font[ana].

M. Fontana, a Neapolitan, first described the compound microscope, consisting of two convex lenses, in his work entitled *Novæ Terrestrium et Celestium Observationes*, which appeared in 1646, but claims to have made the discovery so early as 1618, though he does not adduce any evidence whatever of this fact. Huygens, on the contrary, says, "It does not appear that these microscopes were made in the year 1618, because Sirturus, who published a book that year about the origine and construction of telescopes, would hardly have been silent upon so remarkable an invention, if it had been thus known. Fontana, indeed, lays claim to it from the year 1618, in his book of *Observations*, published in 1646; but the testimony of Lyrsalis, there printed, goes no higher than the year 1625. But that my countryman Drebelius made these compound microscopes at London in the year 1621, I have often been informed by several eye-witnesses, and that he was then reckoned the first inventor of them."

This testimony of Huygens in favour of Drebell, is in direct contradiction to the statement said by Borelli to have been made to the Dutch envoy in 1619.

Galil[eo] [...]he proba[bly] inven[tor] of the mi[cro]scope, [A.]D. 1612.

In consequence of this conflicting evidence, Galileo may be regarded as having the best claim to the invention of the compound microscope. Viviani distinctly informs us in his *Life of Galileo*, that he was led to the invention of the microscope by that of the telescope, and that in the year 1612, he actually sent a microscope in a present to Sigismund King of Poland. Having been dissatisfied with the performance of this instrument, he seems to have devoted himself twelve years afterwards to its improvement; and in a letter to P. Frederigo Cesi, he says that he had delayed to send him the microscope, the use of which he describes, as he had only then brought it to perfection, owing to the difficulty he experienced in making the glasses.[5] In his *Magic of Nature*, Schottus mentions a singular accident which took place with one of the newly invented microscopes.

History.

A Bavarian philosopher, when travelling in the Tyrol, was taken ill on the road and died. The village authorities found a little glass instrument in his pocket, which happened to contain a flea fixed in the focus of the microscope. Upon looking into the eye-glass, they were struck with terror at the sight of the gigantic animal, and the remains of the poor philosopher, who was then proved to be a sorcerer, were pronounced unworthy of Christian burial. Some bold sceptic, however, explored the mystery, and produced the giant which had alarmed them.[1]

Discoveries of Kepler. Born 1571, died 1630.

The name of Kepler, though associated principally with astronomical discovery, will ever be venerated by the cultivators of optical science. His researches, which relate principally to vision and refraction, are contained in his *Paralipomena ad Vitellionem*, published at Frankfort in 1604, and in his *Dioptrica*, already referred to. His discoveries respecting vision, though founded to a certain degree on the views of Maurolycus and Baptista, are nevertheless to a great extent original. He was the first person who actually shewed that distinct and inverted images of external objects are formed upon the retina, as in the camera obscura, by the foci of pencils emanating from every point of the object. He explained all the phenomena of distinct and indistinct vision, and shewed how that indistinctness could be removed by the use of convex and concave glasses. Although D'Alembert[2] has asserted that all optical writers before him had assumed it as an axiom that every visual point is seen in the direction of its visual ray, yet, as Dr. Wells has observed, this assertion is not well founded, for Kepler had long ago maintained that objects are perceived not along the visual rays, but along lines which pass from their pictures on the retina through the centre of the eye; an opinion in which he has been followed by Dechales and Dr. Porterfield, to the last of whom Dr. Reid has by mistake ascribed the discovery of this law. Hence Kepler was led at once to the true theory of erect objects being seen from inverted images, which he considered as the business of the mind, which, when it judges of an impression made on the lower part of an inverted image on the retina, considers it as made by rays proceeding from the higher parts of an erect object, a necessary consequence of his opinion that objects are perceived in lines passing through the centre of the retina. Kepler has wisely declared his ignorance of the manner in which the mind perceives images on the retina, and he blames Vitellio for attempting the solution of a question which does not belong to optics. In order to explain the adaptation of the eye to different distances, Kepler supposed that the ciliary processes draw the sides of the eye towards the crystalline lens, by which change the globe of the eye is elongated, and the retina placed at a greater distance from the crystalline, so as to accommodate the eye to the distinct vision of near objects.

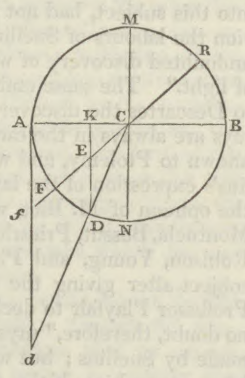
The refraction of light in its passage through different media, is treated at great length, but very unsatisfactorily, by Kepler. Although he failed in his attempts to discover the law of refraction, yet he arrived at certain rules of refraction for glass, which enabled him to discover many of the leading principles of convex and concave lenses. He found, for example, that below 30° of incidence, the angle of refraction was nearly two-thirds of the angle of incidence; that at 90° of incidence the angle of refraction was 42°; and that if the refracted ray fell at a greater obliquity than 42°, upon the interior surface of glass, it would be totally reflected back again into the glass at an angle equal to that of incidence. He then shews, by applying these principles, that plano-convex lenses of glass have their foci at a distance from the lens equal to the diameter of the sphere of which their convex surface is a portion, and that equi-convex lenses have their focal length equal to the radius of the sphere of which their convexities are a portion. When the lens has its surfaee unequally convex, he makes the focal length equal to a mean of the radii of the two spheres. The same properties being proved in reference to concave lenses, Kepler proceeds to find the focus of refracted rays, when they radiate from points at different distances from the lens. He proved also that rays issuing from the focus of a lens will emerge on the other side of it parallel; that if they issue from a point between the focus of the lens, they will diverge after refraction, while those which issue from a point beyond the focus will converge; and, finally, that when the distance of the radiant point is equal to twice the focal length of the lens, the distance of the image will be equal to the distance of the object.

History.

In treating of the refraction of the atmosphere, Kepler remarked that the quantity of refraction would alter if the atmosphere varied in weight, and that it would be different at different temperatures. In one of his letters to Bregger, dated in 1605, on the colours of the rainbow, he makes the following observation:—"The sun's rays are not coloured except with a definite quantity of refraction. Whether you are in the optical chamber, or standing opposite glass globes, or walking in the morning dew, every where it is obvious that a certain and definite angle is observed, under which, when seen in dew, in glass, in water, the sun's splendour appears coloured, and under no other angle. There is no colouring by mere reflexion, without the refraction of a clearer medium."[3]

Snellius discovers the law of refraction, A.D. 1621

Although Tycho and Kepler made many ineffectual attempts to discover the law of refraction, yet the honour of that great discovery was reserved for Willebrord Snellius, Professor of Mathematics at Leyden, who died at the age of thirty-five, leaving behind him a manuscript work on the subject. The doctrine of refraction having become more important after the invention of the telescope, Snellius devoted himself to its investigation, and "after many troublesome experiments and attempts," succeeded in his research. Supposing AB to be the refracting surface of water, an object under the water at D appeared as if it were raised and seen in the line RC. He then produced RC till it intersected at E a line DK drawn parallel to the perpendicular MN, and he asserted that at every angle at which the object D was viewed, it would appear at E, and that CD was to CE in a given ratio, such as 4 to 3, when the refracting body was water. Now this is a true geometrical expression of the law of refraction, though the same truth may be better enunciated in other two ways. If we continue the lines CE CD, till they meet Ad, a line perpendicular to AD, in the points f and d, then on account of the parallels Ad, KD; CD is to CE as Cd is to Cf; but ACd is the complement of the angle of refraction, and ACf the complement of the angle of incidence, and Ad, Af are their secants. Hence it follows from Snellius' result, *that the cosecants of the angles of incidence and refraction are in a constant ratio*, which is a correct mathematical expression of the law of refraction. Again, in the triangle CDE, the sides CD CE are to one another as the Sines of the opposite angles, that is, as the Sines of the angles DEC or KEC, or ECN or RCM, and of CDE or DCN; that is *the sines of the angles of incidence and refraction are*



[1] *Life of Galileo*, Libr. Usef. Knowledge, p. 27.

History.

in a constant ratio, which is the usual and most distinct expression of the law of refraction. In giving this law of Snellius', Huygens has in our opinion forgotten his usual courtesy, when he states that Willebrord Snellius did not "thoroughly comprehend his own invention," and "never imagines that the ratio was the ratio of the Sines." Now we cannot conceive it possible that a man like Snellius, who was a good geometer, was ignorant of the two simple trigonometrical expressions of his geometrical law; and we do not doubt that he preferred his own for two distinct reasons. In the first place, it connects itself with the leading physical phenomena of the apparent rise of the refracted object from D to E, and by substituting CF for CD it furnishes us with a much more simple and accurate method of obtaining by projection the refracted ray from the incident one. If RF for example, is the incident ray, we have only to divide CF into two parts, CE, EF, so that CF is to CE in the constant ratio belonging to the refracting body.

But whether we are right in this conjecture or not, it is an unquestionable truth that Snellius discovered the *true law* of refraction, though he did not express it in trigonometrical language.

Descartes. Born 1596, died 1650.

In the year 1637, about eleven years after the death of Snellius, Descartes published his *Dioptrics*, in which, without ever mentioning the name, or alluding to the labours of Snellius, he announces the true law of refraction expressed in term of the Sines, as the result of his own enquiries. As Snellius's work existed only in manuscript, it was quite possible that Descartes knew nothing of its contents, but Vossius, in his work *De Natura Lucis*, states, that the heirs of Hortensius had communicated freely to Descartes the manuscripts of that professor, among which was that of Snellius's work, and Huygens confirms this allegation when he states in his Dioptrics that he had himself seen the whole manuscript volume of Snellius, and had heard that Descartes had also seen it,[1] and that it was perhaps from hence that he deduced (elicuerit) that measure which consists in the Sines. We should not have entered so minutely into this subject, had not M. Biot[2] thrown into entire oblivion the labours of Snellius, and ascribed to Descartes the undoubted discovery of what he calls "this great property of light." The same eminent philosopher likewise ascribes to Descartes the discovery that the incident and refracted rays are always in the same plane, a truth which was well known to Ptolemy, and which is clearly included in Snellius's expression of the law of refraction. In opposition to the opinion of M. Biot, we must place those of Huygens, Montucla, Bossut, Priestley, David Gregory, Smith, Hutton, Robison, Young, and Playfair; and we shall dismiss the subject after giving the admirable reasons which induced Professor Playfair to decide against Descartes. "There is no doubt, therefore," says he,[3] "that the discovery was first made by Snellius; but whether Descartes derived it from him, or was himself the second discoverer, remains undecided. The question is one of those, where a man's conduct in a particular situation can only be rightly interpreted from his general character and behaviour.

"If Descartes had been uniformly fair and candid in his intercourse with others, one would have rejected with disdain a suspicion of the kind just mentioned. But the truth is, that he appears throughout a jealous and imperious man, always inclined to depress and conceal the merit of others. In speaking of the invention of the telescope, he has told minutely all that is due to accident, but has passed carefully over all that proceeded from design, and has incurred the reproach of relating the origin of that instrument without mentioning the name of Galileo. In the same manner, he omits to speak of the discoveries of Kepler, so nearly connected with his own; and, in treating of the rainbow, he has made no mention of Antonio de Dominis. It is impossible that this should not produce a favourable impression; and hence it is that the warmest admirers of Descartes do not pretend that his conduct towards Snellius can be completely justified.

"Descartes would have conceived his philosophy to be disgraced if it had borrowed any general principle from experience, and he therefore derived, or affected to derive the law of refraction from reasoning or from theory."

Even if Descartes had liberally taken from his optical wreath the law of the Sines, and generously placed the hallowed branch on the brow of the accomplished Snellius, he would have added to his reputation as a man, without shortening his immortality as a philosopher. His Dioptrics consists of ten chapters. The first treats of light, the second of refraction, the third of the eye, the fourth on lenses in general, the fifth on the images formed on the bottom of the eye, the sixth on vision, the seventh on the mode of perfecting vision, the eighth on the figures which transparent bodies require to turn the rays by refraction, suited to all modes of vision, the ninth on microscopes, and the tenth on the mode of polishing glasses. The inability of spherical surfaces to converge rays to one point or focus, had been long known to opticians, and Kepler, though he conjectured that surfaces generated by the revolutions of the conic sections, might have such a property, left the subject just as he found it. Descartes, however, has discussed it in a most ingenious manner, in the eighth chapter of his Dioptrics. He has shewn how parallel, and converging, and diverging rays may be brought to accurate foci by means of ellipsoidal and hyperboloidal surfaces, so that if such surfaces, could be executed by opticians, all optical instruments would receive the highest degree of perfection which they could attain from the removal of spherical aberration. In order to carry this system into effect, he contrived machines for grinding elliptical and hyperbolical lenses, and in the tenth chapter of his Dioptrics he has given perspective drawings and descriptions of them. In the years 1627 and 1628, when he was residing at Paris, M. Mydorgius, with whom he lived on the most intimate habits, urged him to undertake the grinding of hyperbolical and elliptical lenses, and he soon became a great master of the art of glass grinding. He found it necessary, however, to associate with himself in this undertaking an eminent artist, M. Ferrier, who, as an optical instrument maker, was well acquainted both with the theory and the practice of his art. After many failures, a tolerably good hyperbolic convex lens was completed; but the concaves were found to be more difficult; and in consequence of M. Ferrier refusing to accompany Descartes to Franeker, and having occasioned him much needless expence in the erection of his laboratory, a quarrel took place, and the great practical object which they had in view was for a while abandoned. Descartes, however, was sanguine in his expectations, and not aware that there was another aberration more difficult to overcome than that of spherical figure, he expected to be able to make the greatest discoveries in the heavens by means of his new lenses. With the assistance of M. Huygens, the father of the celebrated philosopher, he induced some Dutch artists to renew the attempts of Ferrier; but these and his subsequent endeavours to construct such lenses have failed, though we cannot allow ourselves to think that the attempt is a hopeless one.

Descartes made some interesting observations upon vision, particularly on the method by which we judge of the distances and magnitude of objects; but his principal discovery in physical optics relates to the theory of the rain-

[1] Bossut is incorrect in saying that Huygens *assures us* that Descartes saw the manuscript volume of Hortensius. His words are, "*et Cartesium quoque vidisse accepimus.*" (*Dioptrica*, p. 3.)

History.

bow. He discovered the true cause of the exterior rainbow, and in his *Traité des Meteores*, proves that it was produced by two refractions, and two intermediate reflections within the drop, thus explaining most satisfactorily the faintness of its illumination, and the inversion of its colours. He has clearly shewn also, why the interior bow is 42° in diameter, while the exterior one is 52°; though he did not understand the true origin of the colours. We regret to add, that Descartes gives his explanations of both the interior and exterior bows without ever mentioning the name of Antonio de Dominis, who was the real discoverer of the cause of the rainbow; and our regret is increased, when we are compelled to add, that M. Biot has, contrary to the opinion of all philosophers, given his aid to Descartes in depriving the Italian philosopher of the only discovery which has immortalised his name.[1]

Christopher Scheiner. Born 1575, died 1650.

The science of optics is under considerable obligations to Christopher Scheiner, a Jesuit, and professor of mathematics at Ingolstadt. He completed the theory of vision in so far as he proved by direct experiment that the pictures of external objects were distinctly delineated on the retina. By paring away the coats from the back of the eyes of sheep and oxen, and also the human eye, he made the inverted pictures distinctly visible, and exhibited the experiment publicly at Rome in 1625. In his work entitled *Oculus*, published in 1652, he speaks of the great resemblance of the eye to the camera obscura, and gives various contrivances for erecting the images. He adopts the theory of Kepler respecting the visible direction of objects, and he observed the interesting fact that the pupil of the eye is dilated in viewing distant, and contracted in viewing near objects. In measuring the refractive powers of the humours of the eye, he makes that of the aqueous humour differ little from that of water, and that of the crystalline humour differ little from that of glass, ascribing to the vitreous humour an intermediate refractive power. By tracing the progress of the visual rays through all the humours of the eye, he demonstrates that the retina, and not the crystalline lens, is the seat of vision; and he describes some interesting experiments respecting vision through one or more small apertures. We owe also to Scheiner the interesting experiment of exhibiting on the wall of a darkened room the disc of the sun with all its spots by means of a telescope. When Kircher afterwards describes this appearance he represents the spectator as "fixed with the utmost astonishment."

Double refraction of light discovered by Bartholinus, A. 1669.

A new and very interesting branch of optics had begun to excite the attention of philosophers, namely that of the double refraction of light. Erasmus Bartholinus, a physician at Copenhagen, and the author of several excellent works on geometry, received from some Danish merchants that frequented Iceland, "a crystal stone like a rhombic prism, which, when broken into small pieces, kept the same figure." With this substance, which was called *Iseland spar*, from its locality, Bartholinus made a number of experiments both chemical and optical, and he has published an account of the optical results which he obtained in a small volume which appeared at Copenhagen in 1669, under the title of *Erasmi Bartholini Experimenta Crystalli Islandici, Disdiaclastici quibus mira et insolita Refractio detegitur*, and is dedicated to Frederick III. king of Denmark. In *seventeen* experiments and *twelve* propositions this able and sagacious philosopher has presented us with an excellent summary of the more prominent phenomena of double refraction. He has shewn that Iceland spar has the property of double refraction, that is, of giving two images of all objects seen through it, whether its faces are parallel or inclined, like those of a prism; that the incident light is equally divided between these two pencils; that one of these refractions is performed according to the law of Snellius, the ratio of the Sines being as 1 to 1·667, but that the other is performed according to an extraordinary law which had not previously been observed by philosophers. He observed also a position in which the object appears six-fold, but he did not discover that this took place only in some specimens which were composite or irregular crystals.

Discoveries of Huygens. Born 1629, died 1695.

These discoveries of Bartholinus having been communicated to the Royal Society of London, and printed in No. 67 of their *Transactions*, they attracted the notice of Christian Huygens, a celebrated Dutch philosopher of the finest genius and the highest attainments. Having given a new theory of refraction, he wanted to repeat Bartholinus's experiments principally with the view of ascertaining if they opposed any difficulties to that theory. His work on this subject, entitled *De l'estrange Refraction du Cristal d'Islande*, which forms the 5th chapter of his *Traite de la Lumiére*, was written in 1678, and was read to Cassini, Roemer, and De la Hire, and to several other members of the Royal Academy of Sciences, which he had been invited to join by the liberality of the French king; but it was not published till 1690, when he was resident at the Hague. After giving Bartholinus the credit of having discovered some of the principal phenomena of double refraction, he describes the general properties of Iceland spar in forming two images of objects, and he shews that all the phenomena are related to the axis, or that diagonal of the rhomb, in the direction of which the crystal has no double refraction. He proves that the double refraction, or separation of the two images, gradually increases as the inclination of the refracted ray to the axis increases, and becomes a maximum in a plane at right angles to the axis. In the few preceding chapters of his *Traité de la Lumiére* he had explained all the phenomena of reflexion and refraction upon a new theory, in which he supposes light to be produced in the same manner as sound, by means of undulations propagated in an elastic ethereal medium, an hypothesis revived by Euler and extended by Dr. Young, and now almost universally embraced under the name of the undulatory theory. In applying the same theory to explain the phenomena of double refraction, he supposes the ray produced by the *ordinary* refraction of the medium to be produced by *spherical* undulations propagated through the crystal, while the ray formed by the *extraordinary* refraction is produced by *spheroidal* undulations, the ratio of the two refractions, determining the form of the generating ellipse. Huygens then proceeds to shew that this theory affords, by calculation, results agreeing very exactly with those which he had obtained by direct experiment. This discovery is perhaps the most splendid which has occurred in the history of optical science.

Discovery of the polarisation of light.

When Huygens had finished his researches on double refraction, he discovered what he calls a "wonderful phenomenon,"[2] and, though he acknowledges that we cannot find the cause of it, yet he thinks it proper to indicate the phenomenon that others may inquire into it. This discovery is that of the *polarisation of the light*, which forms the two pencils of Iceland spar, and he confesses that he must add to his theory other suppositions in order to explain it, though he thinks that a theory confirmed by so many proofs will still preserve its plausibility *(vraisemblance)*. Huygens had naturally supposed that the light which composed the two pencils was like all other light, but upon transmitting the two rays formed by one rhomb of calcareous spar through another rhomb, he was astonished to perceive that when the two rhombs were similarly placed as if they had formed one larger one, neither of the rays suffered double refraction in

[1] In his Optics, book ix. p. 147, Sir Isaac gives almost the whole merit of the explanation of the rainbow to De Dominis. He says, "the same explication Descartes hath pursued in his *Meteors*, and *mended that of the exterior bow*."

[2] "Une *phénomène merveilleux*, que j'ay decouvert après avoir écrit tout ce que dessus." (*Traité de la Lumiére*, p. 88.)

History.

passing through the second rhomb, the ordinary ray from the first being only ordinarily refracted by the second rhomb, and the extraordinary ray only extraordinarily refracted. The same thing took place when one of the rhombs, the second, for example, was turned round 90°, with this difference, that the ordinary ray of the first rhomb suffered only extraordinary refraction, and the extraordinary ray only ordinary refraction from the second rhomb. But in all other positions of the second rhomb, excepting these two rectangular ones, the ordinary and extraordinary rays of the first rhomb were each divided into two by the second rhomb, so that there were now *four* rays sometimes of equal but generally of unequal brightness, and such that the light of all the four never exceeded that of the single ray incident on the first rhomb.

Huygens discovered also the double refraction of quartz, or rock crystal, but he committed a great mistake in supposing that its double refraction was regulated by an entirely different law, the light being in this case *propagated through it in two spherical waves, one of which was a little slower than the other.*[1] This result he mentions in his preface as having been obtained after he had read his work to his colleagues in the Academy of Sciences. It is, however, founded on an incorrect observation, as the extraordinary refraction of rock crystal is produced by spheroidal undulations like that of Iceland spar, with this difference only, as afterwards discovered by M. Biot, that the spheroid is a prolate one.

Even if Huygens had not immortalised his name by these great discoveries, his treatises on dioptrics and on halos, and his construction of refracting telescopes of immense size, would have given him the highest reputation. His treatise on dioptrics, which was not published till 1703, among his posthumous works, and which he had begun to prepare at an early period of his life, was particularly admired by Sir Isaac Newton. It contains a copious explanation of the properties of lenses of all forms; and their spherical aberration is treated with much perspicuity, having previously, in the 6th chapter of his *Traité de la Lumière*, published an interesting discussion respecting the figures of transparent bodies for refracting and reflecting light to a single focus. The subject of vision, and the method of assisting long and short-sighted persons by lenses, is ably discussed, and nearly the latter half of the work is devoted to the theory of telescopes, telescopic eye-pieces and microscopes.

Many of these theoretical views Huygens submitted to the test of experiment. Having acquired great expertness in the art of grinding lenses, he executed refracting telescopes 12 and 24 feet in focal length, and afterwards one of 120 and another of 123 feet, with which he discovered Saturn's ring, and the fourth of his satellites. These two last object-glasses he presented to the Royal Society; but as it was impracticable to use tubes of such enormous length, Huygens contrived a method of mounting them without tubes at the top of a long pole. The practical knowledge which he had thus acquired, was published along with his Dioptrics in a work entitled, *Commentarii de formandis poliendisque vitris ad Telescopia*, a considerable part of which was published by Dr. Smith in his optics. Among his posthumous works appeared his *Dissertatio de Cornuis et Parheliis*, a work of great merit, in which he ascribes these phenomena generally to crystals of ice in the upper atmosphere, and a translation of the whole of which Dr. Smith has published in the first volume of his optics.

James Gregory. Born 1638. Died 1675.

Among the eminent men who gave an impulse to optical discovery, we must assign a considerable place to our countryman James Gregory. This eminent mathematician in confirming the experiments of Vitello and Kircher on the angles of refraction, discovered the true law which had previously been found by Snellius. He made the refractive power of water 1·3347, which coincides *exactly* with that of the middle ray between the lines D and E of Fraunhofer. Having discovered before the publication of his work that Descartes' dioptrics contained the law of refraction, he mentions the circumstance, and ascribes his being unacquainted with that work to the "want of new mathematical books," in the library of the college of Aberdeen. Although Baptista Porta appears from the extract which we have already given from his Natural Magic, to have made the nearest possible approach to the invention of the Newtonian reflecting telescope, or rather microscope, yet his experiment excited no notice, and no instrument could be said to have been invented. James Gregory, however, has described what is now known by the name of the Gregorian Reflecting Telescope, at the end of his *Optica Pranata*, published in 1663. It consisted of a parabolic concave mirror perforated at the centre, and having in front of it a small concave elliptic speculum, at a distance a little greater than the sum of their focal lengths. The parallel rays emitted by a remote object formed an image of that object in front of the great mirror, and in its focus; and in the conjugate focus of the small speculum, behind the great speculum, there was formed another image of the object, which was magnified by an eye glass. In 1664, Messrs Rives and Co. English opticians, attempted to construct a six foot Gregorian telescope, under the superintendence of its inventor, but, after a rough trial of it, Mr. Gregory, not aware of the nice adjustments which it required, conceived that the figure of the speculum was defective, and, being on the eve of going abroad, he never even made a tube for the mirrors. Stimulated by the failure of his friend, Newton, "altered," as he says, "the design of the instrument," and "placed the eye glass at the end of the tube rather than at the middle;" and, therefore, he was obliged to reflect the rays to a side by an oval plane speculum. Sir Isaac actually constructed one of these instruments with his own hands, and described it in a letter to a friend, dated the 23d February 1668–9. The aperture of the speculum was one inch, its focal length *six* inches, the eye glass, which was a plano-convex lens, about $\frac{2}{13}$ths of an inch in focal length, and the magnifying power 39 times. He considered it as equal to a three or four feet refractor, and it shewed distinctly the four satellites of Jupiter, and the phases of Venus.[2] Encouraged by his success, he completed another telescope in 1671, which was better than the first, and which is preserved in the library of the Royal Society. The next Newtonian reflecting telescope of any importance, was executed by Mr. John Hadley in 1719 or 1720, with a speculum six inches in diameter, and five feet in focal length; but for a long time the Gregorian form was the most popular in England. About 1672 M. Cassegrain substituted a convex speculum for the small concave one of Gregory, which had the advantage of shortening the tube of the telescope without diminishing the power of the instrument.

Other claimants have arisen for the honour of inventing the reflecting telescope. Father Mersenne in a letter to Descartes in 1637, suggested the idea of using concave mirrors in reflecting telescopes; but Descartes endeavoured to convince him that his views were not likely to succeed. At a later period Fontenelle, in the *History of the Academy of Sciences*, for 1700, has very recklessly ascribed the invention of this instrument to Father Zucchi, an Italian jesuit, who published, at Lyons in 1652, a volume, entitled, *Optica Philosophica*. In this work he says, that he thought of substituting concave specula for object glasses, and having

[1] *Traité* &c. § 20, 21. "Cette double refraction sembloit demander une double émanation d'ondes de lumière, *toutes deux sphériques*, (car les deux refractions sont regulières) et les unes seulement un peu plus lentes que les autres."

[2] Brewster's *Life of Sir Isaac Newton*, p. 26, 27

found a concave metallic mirror in a cabinet of curiosities, he applied to it a concave eye glass, and observed with it celestial and terrestrial objects. As no small speculum was used in this combination, it was neither a Newtonian, Gregorian, nor Cassegrainian telescope; and if Zucchi conceived himself the inventor of a reflecting telescope, why did he conceal it till 1652, and why did he not get a real speculum made to give his idea a fair trial.

Grimaldi discovers the inflexion of light. Born 1619. Died 1663.

Among the discoveries of the 17th century, that of the inflexion of light ranks among the most important. This addition to physical optics was made by Francis Maria Grimaldi, an Italian jesuit, who published an account of it in a work entitled, *Physico-mathesis de Lumine, Coloribus et Iride, aliisque annexis*, which was published at Bologna in 1665, two years after his death. Introducing a ray of the sun's light into a dark room, and through a very small aperture, he remarked, that it formed a cone of light in which all bodies had their shadows larger than if the rays passed in straight lines by their edges. Round these shadows he noticed three coloured fringes becoming narrower as they were farther from the body, and in strong light he observed similar coloured fringes, varying from two to four, according to the distance of the shadow from the body. Hence our author concluded that light is bent from its rectilineal path in passing by the edges of bodies.

When he admitted the light through two small apertures, so near each other that the one luminous cone did not penetrate the other till at a considerable distance from the apertures, he observed that the rays so interfered with one another, as to render the spot illuminated by their *united light more obscure than when it was illuminated by either of them singly.* This extraordinary result is announced in the following proposition: "That a body actually illuminated, may become more obscure by adding a new light to that which it already receives," and may be regarded as the first discovery of the interference of light.

Dr. Hooke. Born 1635. Died 1703.

Dr. Robert Hooke, one of the most ingenious and able men of the century which he adorned, not knowing of the discovery of Grimaldi, communicated to the Royal Society in 1672, an account of "the discovery of a new property of light not mentioned by any optical writers before him." In a subsequent communication in 1675, he draws the following conclusions from his experiments:—1. There is a *deflection* of light, differing both from reflexion and refraction, and seeming to depend on the unequal density of the constituent parts of the ray, whereby the light is dispersed from the place of condensation, and rarified, or gradually diverged into a quadrant. 2. This deflection is made towards the superficies of the opaque body perpendicularly. 3. Those parts of the diverged radiations, which are deflected by the greatest angle from the straight or direct radiation, are the faintest, and those that are deflected by the least angles are the strongest. 4. Rays cutting each other in one common foramen, do not make the angles at the vertex equal. 5. Colours may be made without refraction. 6. The diameter of the sun cannot be taken with common sights. 7. The same rays of light, falling upon the same point of an object, will turn into all sorts of colours by the various inclination of the object. 8. Colours begin to appear when two pulses of light are blended so well, and so near together, that the sense takes them for one."

We owe, also, to Dr. Hooke the first accurate experiments that were made on the subject of thin plates, which, we believe, had been first observed by Mr. Boyle.[1] He investigated the leading phenomena as exhibited in the colours of the soap bubble, and between two plates of glass pressed together. He discovered that the colours depended upon certain thicknesses of the thin plates, but he failed in determining the relation between given thicknesses and given colours. He succeeded in splitting mica into plates of extreme tenuity, as to give the most brilliant colours, one giving a *yellow*, another a *blue*, and the two together a *deep purple.* In his *Micrographia*, printed about seven years before any of Newton's experiments were made on the same subject, Dr. Hooke has published the following remarkable explanation of these phenomena, which coincides in a singular manner, with that which is now universally received: "It is most evident, says he, that the reflection from the under or further side of the body, is the principal cause of the production of these colours. Let the ray fall obliquely on the thin plate, part thereof is reflected back by the first superficies,—part refracted to the second surface, whence it is reflected and refracted again. So that, after two refractions and one reflection, there is propagated a kind of fainter ray, and by reason of the time spent in passing and repassing, this fainter pulse comes behind the former reflected pulse; so that hereby, (the surfaces being so near together that the eye cannot discriminate them from one) this confused or duplicated pulse, whose strongest part precedes, and whose weakest follows, does produce on the retina the sensation of a yellow. If these surfaces are further removed asunder, the weaker pulse may become coincident with the reflection of the second, or next following pulse, from the first surface, and lagg behind that also, and be coincident with the third, fourth, fifth, sixth, seventh, or eighth; so that, if there be a thin transparent body, that from the greatest thinness requisite to produce colours, does by degrees grow to the greatest thickness,—the colours shall be so often repeated, as the weaker pulse does lose paces with its primary or first pulse, and is coincident with a subsequent pulse. And this, as it is coincident, or follows from the first hypothesis I took of colours, so upon experiment have I found it in multitudes of instances that seem to prove it."

Galileo, and the philosophers of the Accademia del Cimento, had proposed to measure the velocity of light by means of a base on the surface of the globe; but such an attempt was utterly hopeless, and it was only in a wider range that this problem could be solved. Baffled in finding an explanation of some irregularity in the emersion of the first satellite of Jupiter, Cassini and Roemer had concluded that it depended on the distance of Jupiter from the earth, and that in order to explain it it was necessary to suppose, that the light of the satellite required ten or eleven minutes to move across the earth's orbit. This happy idea seems to have first occurred to Cassini, but he speedily abandoned it, while Roemer pertinaciously cherished the hypothesis, and at last immortalised himself by demonstrating in the most rigorous manner that light moves through the diameter of the earth's orbit, a distance of 190 millions of miles, in eleven minutes.

Roemer. Born 1644. Died 1710.

Passing over the valuable researches of Tschirnhausen, a Saxon nobleman, on caustic curves, which had been previously discovered, and the discoveries of Mariotte and de la Hiré, respecting the seat of vision, which have not terminated in any satisfactory conclusions, we are brought to one of the most brilliant periods of optical discovery.

Discoveries of Newton. Born 1642. Died 1727.

In the year 1665, Sir Isaac Newton, when only 23 years of age, bought three prisms, but he does not seem to have made any particular experiments with them. In 1666, however, he bought another, with which he proposed to repeat Grimaldi's experiment, on the elongation of the sun's image produced by the prism. In the course of this and the two or three subsequent years, he made and perfected his great discovery of the *different refrangibility of light*, which he communicated to the Royal Society on the 6th of February 1672, having, on the 18th of January, announced it as "the oddest if not the most considerable detection

[1] *Experiments and Observations upon Colours*, 1663.

History.

which hath hitherto been made in the operations of nature." Having found that refraction could not be produced without colour, he was led to direct his attention to the perfection of the reflecting telescope, and produced the instruments which we have already mentioned. Another result of this discovery was the completion of the theory of the rainbow, the origin of the colours of which had hitherto perplexed philosophers.

The next optical discovery made by Sir Isaac Newton, related to the *colours of thin plates*, or of thin transparent bodies, such as the soap bubble. We have already seen that Dr. Hooke had made some progress, both in observing the phenomena and in investigating the cause of such colours; but it is to Newton that we owe an elaborate analysis of the subject. In a letter from Sir Isaac to Dr. Hooke, dated 5th February 1676, he acknowledges that the latter had previously observed "the dilatation of the coloured rays by the obliquation of the eye, and the opposition of a black spot at the contact of two convex glasses, and at the top of a water bubble," (soap bubble). In the course of his experiments on thin plates, Newton was led to the discovery of the colours of thick plates, and he devised a theory for explaining both classes of phenomena, known by the name of the theory of fits of easy reflexion and transmission. This theory, remarkable for its ingenuity, is now no longer an expression of the phenomena, and has given way to the theory of undulations, which Hooke had the sagacity to anticipate as affording the true cause of the colours of thin plates.

Early in 1676, Newton communicated to the Royal Society his *Theory of the Colours of Natural Bodies*, in which he ascribes all the varieties of colour exhibited in nature to the circumstance "that the transparent parts of bodies, according to their several sizes, reflect rays of one colour and transmit those of another, on the same grounds that thin plates or bubbles do reflect or transmit those rays." This theory, perhaps the finest of all Newton's optical speculations, has met with much opposition. It was controverted by Mr. Delaval, Sir John Herschel, and others, in its leading propositions; but some recent discoveries afford us reason for believing that the principal objections to it are groundless, and that with some modifications it may yet be placed among the finest generalizations in science.

Sir Isaac Newton's experiments on the inflexion of light were never finished by their author. His observations were limited, and his theory incorrect; and indeed it was only from the hands of those who adopted the undulating system that a true explanation of the phenomena could be expected.

The experiments of our author on the refractive powers of bodies, from which he anticipated that the diamond "was probably an unctuous substance coagulated," have on this account been regarded with high favour, while his few observations on the double refraction and polarisation of light have almost disappeared from the history of optics.[1]

Achromatic telescope.

The next great step in the history of optical discovery is the invention of the *achromatic telescope*, or telescopes which are free from colour. When Sir Isaac Newton found that he could not produce refraction without colour, he abandoned the improvement of the refracting telecide as hopeless, and devoted himself to the construction of reflectors. The opinion at which he had arrived respecting the impracticability of refracting light without colouring it, was, however, an erroneous one, which he had deduced from an incorrect observation of the relative length of the prismatic spectra formed by different bodies, when the mean refraction was the same. In less than two years after Newton's death, namely, in 1729, Mr. Chester More Hall, of More Hall in Essex, was led by the study of the human eye, which he erroneously conceived to be achromatic, to consider the possibility of constructing a telescope by an analogous combination of media. After many experiments, he found two kinds of glass capable of producing, by their combination, refraction without colour.[2] About 1733 he completed several such object-glasses, which, with a focal length of twenty inches, bore an aperture of more than two-and-a-half inches, one of which was long afterwards in the possession of the Rev. Mr. Smith of Charlotte Street, Rathbone Place, and was found to be achromatic. Another of Mr. Hall's telescopes was in the possession of Mr. Ayscough, optician in Ludgate Hill, in 1754. Mr. Hall, however, kept his invention a secret; none of his instruments were either sold or exhibited for sale, and those into whose hands they fell do not seem to have discovered either their principle or their value.

Without calling in question the merits of Mr. Hall, we must do justice to those of Mr. John Dollond, an undoubted inventor of the achromatic telescope, who, unacquainted with the instruments of Mr. Hall, proceeded step by step, in a scientific progression, till he invented and constructed the achromatic telescope in 1757. To this eminent individual, and the other members of his family, we owe the construction of many of the finest instruments by which the science of astronomy has been so much promoted. Mr. Peter Dollond, the son of John Dollond, first suggested and used the triple object-glass, in which a better correction of the spherical aberration was effected, by placing the concave flint glass between two convex lenses of crown glass.

The mathematical world owe many obligations to Euler, Clairaut, D'Alembert, and Boscovich, for their able investigations of the theory of achromatism, but their investigations did not prove of any practical value; and it has been justly stated by Sir John Herschel, "that from all the abstruse researches of Clairaut, Euler, and D'Alembert, and other celebrated geometers, nothing hitherto has resulted beyond a mass of complicated formulas, which, though confessedly exact in theory, have never yet been made the basis of construction for a single good instrument, and remains therefore totally inapplicable, or at least unapplied in practice."[3]

No attempt had hitherto been made to measure the intensity of different lights emanating either directly from luminous bodies, or when transmitted through or reflected from different bodies. This subject, to which the name of Photometry has been given, was begun by Huygens and P. F. Marie, who describes an instrument called a *lucimeter*; but it is to M. Bouguer and M. Lambert that we owe the most scientific and complete investigation of this class of facts.

Bouguer's earliest experiments were published in 1729, in his *Optical Essay on the Gradation of Light*, which was republished in 1760, much augmented and improved, under the title of *Traité d'Optique sur la Gradation de la Lumière*.

---

1 We must refer our readers for a full and elaborate account of Newton's optical discoveries to a new work, entitled *Memoirs of the Life, Writings, and Discoveries of Sir Isaac Newton*, in which Sir David Brewster is now occupied, having had access to the interesting collection of the papers of Sir Isaac, in the possession of the Earl of Portsmouth.

2 Mr. Hall might have got this hint from David Gregory's *Catoptrics*, published at Edinburgh in 1713. "But if," says he, "on account of physical difficulties in grinding and polishing proper specula, we should still use lenses, *it would perhaps be useful to employ media of different density to compose the object-glass*, as we see done by nature in the structure of the eye, where the crystalline humour, (of almost the same refractive power as glass), is joined by nature, who does nothing in vain, with the aqueous and vitreous humours, (not unlike water in their refractive power), to paint the image as distinctly as possible in the bottom of the eye." Gregory's *Catoptrics*, prop. xxiv. Scholium. Dr. Brown's translation of the preceding passage is very incorrect.

3 *Phil. Trans.* 1821, p. 222.

History.

Lambert. Born 1728. Died 1777.

Bouguer was followed in this inquiry by M Lambert, an able German mathematician, who published an account of his researches at Augsburg in 1760, in a duodecimo volume of 547 pages, entitled *Photometria seu de Mensura et Gradibus Luminis, colorum et umbræ.* It is divided into seven parts: 1. On the modifications and degrees of direct light, and of its brightness and illuminating power; 2. Experiments and calculations on the modifications of light depending on transparent bodies, but chiefly glass; 3. Experiments and calculations respecting the modifications of light depending on the opacity of bodies; 4. Calculations and experiments on the sense of light, and its apparent brightness; 5. On the dispersion of light passing through diaphanous media, chiefly the earth's atmosphere; 6. Calculations respecting the illumination of the planetary system; and, 7. On the modifications and degrees of heterogenous and relative light, or the light of colours and shadow.

Sir William Herschel. Born 1738. Died 1822.

Passing over the minor labours of Porterfield, Turner, Mazeas, Dutour, Buffon, Scheiffer, Darwin, Melville, Mitchell, and others we come to the period of Sir William Herschel. Since the discovery of the belts and nearest satellites of Saturn, no discovery of any importance had been made respecting the natural history of the heavens. At the age of 36, when Sir William was residing at Bath, he devoted much of his time to the construction of telescopes; and the following account of his progress is too interesting to be given in any other language than his own,—"When I resided," says he, "at Bath, I had long been acquainted with the theory of optics and mechanism, and wanted only that experience which is so necessary in the practical part of these sciences. This I acquired by degrees at that place, where, in my leisure hours, by way of amusement, I made for myself several two feet, five feet, seven feet, ten feet, and twenty feet Newtonian telescopes, besides others of the Gregorian form, of eight inches, twelve inches, two feet, three feet, five feet, and ten feet, focal length. My way of doing these instruments at that time, when the direct method of giving the figure of any one of the conic sections to specula was still unknown to me, was to have many mirrors of each sort cast, and to finish them all as well as I could, then to select by trial the best of them, which I preserved; the rest were put by to be re-polished. In this manner, I made no less than two hundred seven-feet, one hundred and fifty ten-feet, and about eighty twenty-feet, not to mention those of the Gregorian form, or of the construction of Dr. Smith's reflecting microscope, of which I also made a great number. My mechanical amusements went hand in hand with the optical ones. The number of stands I invented for these telescopes it would not be easy to assign. I contrived and delineated them of different forms, and executed the most promising of the designs. To these labours we owe my seven-feet Newtonian telescope stand, which was brought to its present convenient construction about 1778."

By means of these instruments, with which he surveyed the heavens with unwearied diligence, he discovered the Georgium Sidus, with six satellites, two new satellites circulating round Saturn, the quintuple belt and double ring of the same planet, and various other astronomical phenomena of the highest interest. In 1783 he finished a twenty-feet reflector, with an aperture of $18\frac{7}{10}$ inches, and formed the design of constructing a still larger instrument. On the recommendation of Sir Joseph Banks, his Majesty George III. agreed to defray the expense of a large telescope, and under his munificent patronage, which has never since been imitated by his successors, Sir William began in 1785, and completed on the 27th August 1789, a reflecting telescope forty feet in focal length, having its great speculum *four feet* in breadth three-and-a-half inches thick, and weighing, when newly cast, 2118 pounds. On the 28th of August, the day after this gigantic instrument was erected, Sir William discovered a new satellite of Saturn, and in the same year another satellite, both of which were nearer the body of the planet than the other five discovered by Huygens and Cassini. In this manner the telescope, which was a toy in the hands of Galileo, became with Sir William Herschel a vast machine, carrying the observer himself, and directed and moved by appropriate mechanism.

Dr. Blair. A.D. 1787. Died 1829.

An improvement in the achromatic telescope, of great value, though not yet brought into practical use, was made by Dr. Robert Blair. Although in the achromatic telescope composed of crown and flint glass, the colour was as completely corrected as it was possible to do with such lenses, yet it had long been observed that there were residual colours, which formed what are called a secondary spectrum, and which arise from the coloured spaces in the spectrum, produced by crown glass not having the same size as those in a spectrum of equal length produced by flint glass. Various attempts had been made in vain to obtain other substances, in which this *irrationality*, as it was called, of the coloured spaces did not exist; and Dr. Blair was hence led to attempt the removal of the secondary spectrum by other means. The plan which he adopted was the following. He made each lens of his compound object-glass achromatic, but in such a way that the secondary spectrum produced by the one should be corrected by the secondary spectrum produced by the other. Such an object-glass required two fluid media and three lenses of glass, and Dr. Blair succeeded in constructing them so as to be perfectly free from all secondary colour. In the course of his experiments, however, he was fortunate enough to discover that the muriatic acid mixed in proper proportions with metallic antimony, or butter of antimony, as it was called, gave a spectrum, in which the colours had exactly the same proportion as crown glass; and hence, by enclosing this fluid between two lenses of crown glass, the one next the object being plano-convex and the other a meniscus, he obtained an object-glass in which the rays of different colours were bent from their rectilineal course with the same equality and regularity as in reflexions. To such an object-glass he proposed to give the name of *aplanatic*, to indicate the entire removal of all aberration. Dr. Robison informs us that one of these telescopes, which did not exceed *fifteen inches* in length, equalled in all respects, if it did not surpass, the best of Dollond's achromatic telescopes *forty-two inches* long. After the death of Dr. Blair, his son, Mr. Archibald Blair, attempted in vain to produce instruments of the same perfection. Had this young man lived, he might have executed something better, but he was cut off at an early age, and has left to the Royal Society of Edinburgh an account of his father's methods, which we hope may prove useful to science.

Dr. Thomas Young. Born 1773. Died 1829.

Hitherto the undulatory theory of light as proposed by Huygens and supported by Hooke and Euler, had met with few adherents; and the reputation of Newton had given to the theory of emission an adventitious authority to which it was not entitled. Dr. Young, however, boldly threw down the gauntlet and maintained the theory of Huygens with the greatest ingenuity and talent. In his paper of 1800, entitled *Outlines of Experiments and Observations on Sound and Light*, he shews that light has a strong analogy with sound, and that it is produced by the undulation of a highly elastic etherial medium which pervades all nature. In another paper, which he published in 1801, *On the Theory of Light and Colours*, he applies the theory of undulations to the explanation of natural phenomena; and lays down the following hypotheses: 1. That a luminiferous ether pervades the universe, rare and elastic in a high degree. 2. That undulations are excited in this ether whenever a body becomes luminous. 3. That the sensation of different colours depends on the different frequency of vibrations excited by light in the retina; and, 4th, that all material bodies are to be considered, with respect to the phenomena of light, as consisting of particles so remote from each other as to allow the

History.

etherial medium to pervade them with perfect freedom, and either to retain it in a state of greater density and of equal elasticity, or to constitute together with the medium an aggregate which may be considered as denser but not more elastic. He then proceeds to demonstrate in nine propositions, some of the leading truths in the theory, applying them in corollaries to the colour of striated surfaces, the colours of thin plates, the colours of thick plates, and the colours produced by inflexion. In 1802, Dr. Young published *An account of some causes of the Production of Colours not hitherto observed.* The cases described in this paper are the colours of delicate fibres and of mixed plates. The first he explains by the interference of two portions of light, one reflected from the fibre and the other bending round its opposite side, and at last coinciding nearly in direction with the former portion. The colours of mixed plates are those produced when moisture, butter, or tallow, are placed between two plates of glass, so that portions of air are intermixed with these substances. A candle seen through such a medium is surrounded with a sort of halo, and Dr. Young considers the colours as produced by the light which passes through one of the media, moving with greater velocity so as to anticipate the light which comes more slowly through the other.

In 1803, Dr. Young published what may be considered as his principal paper, entitled *Experiments and Calculations relating to Physical Optics*, in which he has given an experimental demonstration of the general law of interference. By intercepting the rays which passed on one side of a body which formed fringes by reflexion, the fringes disappeared whether the interception was made on one side or the other of the body. This admirable experiment established the truth of his law of interference, and paved the way for those splendid generalizations respecting the undulatory theory which have so widely enlarged the boundaries of optics.

In April 1814, in a review of Malus, Biot, and Brewster's *Experiments on Light*, which he contributed to the *Quarterly Review*, he first published his explanation of the colours of crystallised plates produced by polarised light by the law of interference, an explanation which is now universally admitted. In the article on *Chromatics*, which Dr. Young contributed to this work, the reader will find a full account of the discoveries to which the law of interference has been so successfully applied. One of the most important applications of the undulatory theory was published in that article for the first time. Dr. Young has there given an expression of the velocity of reflected light at a perpendicular incidence from bodies of various refractive powers, which is a simple function of the index of refraction.

In giving an account of Sir William Herschel's discoveries, we have not mentioned his discovery of invisible heating rays beyond the red extremity of the spectrum, because we have ourselves succeeded in discovering the luminous rays at that part of the spectrum. In repeating Sir W. Herschel's experiments, M. Ritter of Jena placed muriate of silver in different parts of the spectrum, and found that it soon became black *beyond* the violet extremity, less black in the violet rays, becoming still less black in the blue and green, and so on till the blackness vanished. When he used muriate of silver, slightly blackened or disoxygenated, its white or original colour was partly retained by the red, and still more by the supposed invisible rays beyond it. In these experiments of Ritter's, as well as in those of Sir W. Herschel, the solar spectrum, when seen by the eye, as thrown upon paper, is extremely short. A great part of the violet extremity as well as the red extremity is invisible, so that when the thermometer and the muriate of silver seemed to be wholly out of the spectrum, they were completely within the violet and the red spaces, as we have placed beyond a doubt by

Ritter, A.D. 1801.

comparing the length of a spectrum on paper with that which can be rendered visible by directly looking through a telescope at a highly magnified one.

Histo[ry]

Dr. W[ol]laston. Born [...] Died [...]

Without knowing of the experiments of Ritter, Dr. Wollaston discovered the chemical effects which exist at the violet end of the spectrum; but the merit of this experiment decidedly belongs to Scheele, who discovered that muriate of silver was more blackened in the violet rays than in any other part of the spectrum. The principal discovery in optics, which we owe to Dr. Wollaston is his method of observing the spectrum, and his discovery of *five* fixed lines in it. The following is his own description of it: "I cannot conclude these observations on dispersion without remarking that the colours into which a beam of white light is separable by refraction, appear to me to be neither seven, as they usually are seen in the rainbow, nor reducible by any means (that I can find) to three, as some persons have conceived; but that, by employing a very narrow pencil of light, four primary divisions of the prismatic spectrum may be seen with a degree of distinctness that, I believe, has not been described nor observed before.

"If a beam of day-light be admitted into a dark room by a crevice $\frac{1}{20}$ of an inch broad, and received by the eye at a distance of ten or twelve feet, through a prism of flint glass *free from veins*, held near the eye, the beam is seen to be separated into the four following colours only, red, yellowish green, blue, and violet; in the proportion represented in the figure.

"The line A that bounds the red side of the spectrum is somewhat confused, which seems, in part owing to the want of power in the eye to converge red light. The line B, between red and green, in a certain position of the prism, is perfectly distinct; so also are D and E, the two limits of violet. But C, the limit of green and blue, is not so clearly marked as the red; and there are also, on each side of this limit, other distinct dark lines, *f* and *g*, either of which in an imperfect experiment, might be mistaken for the boundary of these colours.

"The position of the prism in which the colours are most clearly divided is when the incident light makes about equal angles with two of its sides. I thus found that the spaces AB, BC, CD, DE, occupied by them, were nearly as the numbers 16, 23, 36, 25.

"Since the proportions of these colours to each other have been supposed by Dr. Blair to vary according to the medium by which they are produced. I have compared with this appearance the coloured images caused by prismatic vessels, containing substances supposed by him to differ most in this respect, such as strong but colourless nitric acid, rectified oil of turpentine, very pale oil of sassafras, and Canada balsam also nearly colourless. With each of these I have found the same arrangement of the four colours, and, in similar positions of the prisms, as nearly as I could judge, the same proportions of them.[1]

"But, when the inclination of any prism is altered so as to increase the dispersion of the colours, the proportions of them to each other are thus also changed, so that the spaces AC and CE, instead of being as before 39 and 61, may be found altered as far as 42 and 58." These interesting observations are appended to his *Method of examining Refractive and Dispersive Powers by Prismatic Reflection*, which was published in the *Phil. Trans.* for 1802.

In the year 1800, Dr. Wollaston published in the *Philosophical Transactions* some interesting experiments and observations *On Double Images caused by Atmospherical Refraction*, and in the same work for 1802, he communicated a series of measures *On the Oblique Refraction of Iceland Crystal* in different planes, which he found, as the measures taken by Huygens had done before,

[1] The observations in this paragraph are quite incorrect. Dr. Blair's results to which they stand opposed have been placed beyond the reach of doubt.

History.

to agree in a remarkable manner with the beautiful law established by the Dutch philosopher.

These researches of Dr. Wollaston, but particularly the discoveries of Dr. Young, had about this time drawn the attention of the philosophers of France to the subject of double refraction. Laplace had considered the deviation of the extraordinary ray, as due to the action of the attractive and repulsive forces by which Newton and his successors had endeavoured to explain the ordinary refraction and reflexion of light; and the Institute of France were thus led in 1808 to propose the double refraction of light as the subject of a prize to be adjudged in 1810. Among the few memoirs which were sent in competition for this prize, that of E. L. Malus, colonel of the imperial corps of engineers was the successful one. After his return from the fatal expedition to Egypt he had composed his *Traité d'Optique*, a work of great merit; but as soon as the subject of double refraction was announced, he devoted himself to the inquiry with equal ardour and success. Residing in the Rue des Enfers, in Paris, he happened to view, through a doubly refracting prism, the windows of the palace of the Luxembourg, which were then reflecting to his eye the rays of the setting sun, and, on happening to turn round the prism, he was surprised to perceive that one of the two images of each window vanished in every quadrant of the rotation of the prism. In pursuing this remarkable experiment he was conducted to the splendid discovery which forms an epoch in the history of optics, *that when a pencil of light is reflected by a surface of glass at an angle of 54° 35′, or of water at an angle of 52° 45′, the reflected light possesses all the characters of one of the pencils formed by double refraction.* Hence the pencil was said to be *polarised* by reflexion. When a pencil thus reflected was made to fall on another surface of the same kind at the same angle, but so that the plane of the second reflexion was at right angles to the plane of the first, then not a single ray of the light suffered reflexion, the whole pencil suffering refraction only. When the light fell upon a plate of glass the light reflected from the second surface acquired the same property.

Malus. Born 1775. Died 1812.

On the 11th of March 1811, Malus announced to the Institute, that, when a pencil of light was thus polarised by reflexion, the light which was at the same time transmitted through the surface consisted of a portion of light polarised in an opposite direction, and proportional to that which was reflected, and of another portion not modified, which preserves the properties of direct light. This last portion becomes less and less by transmitting the ray through a number of plates in succession till the transmitted pencil is wholly polarised in one direction.

Malus likewise made several experiments on the polarisation of light by metals, and he was led to the conclusion, that the difference between transparent and metallic bodies was, that the former refract all the light polarised in one direction, and reflect all that is polarised in the other, while metallic bodies reflect what they polarise in both directions.

In a series of experiments on crystals and organised substances, communicated to the Institute on the 19th August 1811, Malus found that they all *depolarised* a pencil of polarised light; that is, a pencil of polarised light which refused to be reflected by another surface properly placed, recovered its power of being reflected after being transmitted through crystals and organised substances. All crystals which did not crystallise in the form of the cube or the regular octohedron were found to possess the property of depolarisation; and the organised substances which he found to possess the same property, were the transparent and fibrous portions of leaves and flowers, the pellicles which cover the hazel, silken and woollen fibres, white hairs, scales, horn, ivory, feathers, the skins of quadrupeds and fishes, shells, and the whiskers of a whale. Malus intended to prosecute this subject to a greater extent, but his brilliant career of discovery terminated by his death on the 7th February 1812.

Discoveries of M. Arago. Born 1786.

The loss of Malus, great as it was felt to be, was immediately supplied by his distinguished colleague in the Institute, M. Arago, who has added to this and other departments of science so many brilliant discoveries. On the 11th of August 1811, before the death of Malus, M. Arago communicated to the Institute a memoir "On a particular modification which the luminous rays experience in their passage through certain transparent bodies."[1] Upon exposing thin plates of sulphate of lime, mica, and rock-crystal, to polarised light, and subsequently analyzing the light which they transmitted by a prism of calcareous spar, M. Arago observed the most splendid complementary colours changing with every variation in the inclination of the plate. When the light was incident perpendicularly, and the plate turned round in its own plane, the colours were in all positions the same, though they varied in intensity. He found two positions at right angles to each other, in which the crystal gave no colour, and these positions were those in which the principal section of the crystal was perpendicular to, or coincident with the plane of primitive polarisation. Setting out from these positions, the intensity of the ray gradually increased, and became a maximum at an angle of 45° to that plane. When the crystallised plate was fixed, and the analysing plate turned round so as to vary the inclination of the plane of reflexion from it, to that of the fixed plate which polarised the light primitively, the change in the colours was most beautiful. M. Arago observed that the colour reflected in any one position of the analysing plate was *complementary* to the colour reflected in the perpendicular position. He also found that the power of depolarising the different colours diminished with the thickness of the plate, and he reduced mica to such a degree of thinness that it depolarised no colours at all. In studying the same phenomena in sulphate of lime and rock crystal, M. Arago was led to the conclusion that the colours depended on some other cause than that of the thinness of the plate. M. Arago likewise discovered the depolarising property in a piece of flint glass, about three quarters of an inch in thickness.

We owe also to M. Arago the discovery of circular polarisation in quartz, which he made in 1811. By transmitting polarised light along the axis of the prism he observed the tints to be different in their nature from the ordinary tints of the mineral, although they increased and diminished with the thickness of the plate. When analysed with a prism of Iceland spar, he observed that the true images had complementary colours as in the ordinary tints, and that the colours changed, descending in Newton's scale as the prism was turned round, so that if the colour of the extraordinary image was *red*, it became in succession *orange yellow, green*, and *violet*; and hence he drew the important inference that the differently coloured rays had been polarised in different planes in passing along the axis of the crystal. M. Arago's duties in the Observatory prevented him from pursuing these valuable discoveries with that continuity of labour which they demanded.

A very important discovery was made by M. Arago respecting the colours of thin plates.[2] When the rings of thin plates were examined through a rhomb of Iceland spar, M. Arago discovered that when the principal section of the rhomb was parallel and perpendicular to the plane of incidence, the intensity of the light in one of the images varied with the incidence, and that this image vanished altogether when the pencil of light was inclined 35° to the surface, or when it was incident at the maximum polarising angle. This result was the same, whether he examined the reflect-

[1] Mémoires de l'Institut 1811, part i. p. 93–134.

[2] Mémoires d'Arcuel, tom. iii. *Sur les Couleurs des Lames Minces.*

History.

ed or the transmitted rings. Hence he inferred that the light of both the systems of rings was polarised in the plane of incidence, at the polarising angle for glass. M. Arago has likewise shewn that the colours of the reflected and transmitted rays are complementary, and that their intensities are exactly equal, completely neutralising each other or forming white light when they are superposed. The most interesting experiment, however, made by M. Arago, is that in which he examined the rings when a convex lens was pressed upon a metallic reflector. When viewed with a prism of Iceland spar, as before, one of the two images vanished at the maximum polarising angle of the glass, but the phenomena were different above and below this angle. At less angles, the dimensions and the colours of the rings were the same in both images, which differed only in the quantity of their light; but at greater angles, the rings in the two images had their colours complementary, the one beginning from a white centre, and the other from a black one.

We have already seen that Dr. Young first applied the principle of interference to explain the colours of crystallised plates; but he did not explain why these colours are not produced excepting with polarised light. MM. Arago and Fresnel entered upon this inquiry, and obtained a satisfactory solution of the difficulty. They found that two rays of light polarised in the same plane, produced fringes by their interference as in common light; that no interference at all takes place when these planes are at right angles to each other: and that at an intermediate inclination, the interference is diminished, and the fringes decrease in intensity. In following out these interesting results, they found that two oppositely polarised pencils will not interfere even when their planes are made to coincide, unless they belong to a pencil which had been wholly polarised in one plane.

We owe also to M. Arago the beautiful discovery that the quantity of polarised light in the reflected and transmitted pencils of common plates are exactly equal.

We are indebted likewise to M. Arago for some important results respecting the interference of light. We have already seen that the interior fringes formed by diffraction disappear when the light which passes by one side of the inflecting body is stopped. M. Arago observed that these fringes were displaced by making the same light pass through a thin plate of some transparent substance, and that the bands were always shifted to the side on which the plate was placed. The amount of this displacement determines the velocity of light in the interposed medium, and consequently gives us a measure of the refractive power of that body with the highest degree of accuracy.

In conjunction with M. Biot, M. Arago published a valuable series of experiments on the density and refractive power of *nine* gaseous bodies measured in relation to atmospheric air taken as unity. Hydrogen stood at the head of the table, with a refractive index equal to 6·61436, (or 7·0335 if we use the density given by Berzelius) whilst oxygen stood at the foot of the table with a refractive index of 0.8616.

M. Biot. Born 1774.

Among the most successful cultivators of physical optics, M. Biot holds a distinguished place. His attention was first directed to the colours of crystalline plates discovered by M. Arago, and by nice instruments and indefatigable labour he determined the general laws of the phenomenon in reference to the thickness of the plates, and the composition of the tints as observed in sulphate of lime and rock crystal, calcareous spar, and arragonite. He observed that at a perpendicular incidence the two colours correspond to those seen by reflexion and transmission in thin plates of air, and he concluded that the thicknesses at which these colours were developed, were proportional to the thickness of the plate of air which gave the same tint in Newton's scale. These thicknesses were found to vary with the nature of the crystal, and were always much greater than the thicknesses of thin plates which gave the same tints. He had at first supposed that at oblique incidences the changes of colour followed the same law as in thin plates, but he afterwards found that the tint depended on the thickness of the crystal traversed by the refracted ray, and as the square of the sine of the angle which the direction of the ray formed with the optic axis. In these experiments M. Biot considered arragonite, sulphate of lime, topaz, and mica, as all having one axis of double refraction like calcareous spar.

In order to explain these various phenomena, M. Biot communicated to the Institute in 1812[1] his ingenious theory of *Moveable Polarisation*. In this theory the particles of a polarised ray are supposed to preserve their primitive polarisation till they reach a certain depth in the crystal, when a succession of isochronous oscillations round their centre of gravity take place, the axes of polarisation being carried alternately to each side of the axis of the crystal. The depth through which the particle is carried during each of these oscillations, is assumed to be twice the depth through which it has passed before the oscillations began. When the ray emerges from the crystalline plate, the oscillations are supposed to stop, and the ray assumes a *fixed polarisation*, (in which the axes of the particles are arranged in two rectangular directions) as if the last oscillation had been completed when it quitted the plate.

The remarkable colours discovered by M. Arago along the axis of quartz, were carefully studied by M. Biot, and he and M. Seebeck, nearly about the same time discovered the existence of the very same colours in several essential oils and solutions, such as oil of turpentine, oil of laurel, oil of lemons, syrup of sugar, the two first turning the planes of polarisation from right to left, and the two last from left to right. In a memoir laid before the Institute in 1818, he has shewn that the angular rotation of the plane of polarisation is directly proportional to the thickness of the plate and inversely to the square of the length of the fits as given by Newton. He then concludes that this property of turning the particles of light round their centres of gravity resides in the ultimate particles of solid or fluid bodies, that it is necessary to their very existence, and that it is entirely independent of their mutual distances and mode of aggregation.

M. Biot afterwards resumed this subject, and extended his researches to a great variety of substances; and he has still more recently employed circular polarisation in detecting the constituents of particular vegetable substances, where chemical analysis had partly or wholly failed. He has shewn that the soluble portion of plants, or the farinaceous matter of grain and roots, to which he has given the name of *dextrine*, and which M. Raspail had considered to be of the nature of gum, turns the planes of polarisation more powerfully to the *right* (hence the name *dextrine)* than the syrups of *cane sugar;* and that all the *gums*, and the syrups of the *sugar of grapes*, turn the planes of polarisation to the left. M. Biot has also applied the same method of research in ascertaining the changes which take place in the sap of trees, and in analysing the processes of vegetation which are concerned in the growth of wheat and rye. His researches are of great practical value in an agricultural point of view, and ought to impress on those whom it most concerns, the important truth, that the most recondite discoveries in science will sooner or later find an useful application.

One of the most important discoveries made by M. Biot was the true nature of the double refraction and polarisation in quartz, which Huygens had been unable to develope. M.

[1] *Sur un nouveau genre d'Oscillation que les Molecules de la Lumière eprouvent en traversant certains cristaux.*

Biot found that it differed from that of calcareous spar, in having the phenomena regulated by a *prolate* in place of an *oblate* spheroid, the least refracted image being the ordinary ray in quartz, and the extraordinary one in Iceland spar.

Sir David Brewster.

Whilst these valuable researches were carrying on in France, Sir David Brewster was occupied with the same subject in Scotland. In his *Treatise on New Philosophical Instruments*, published in the beginning of 1813, he has shewn that chromate of lead and realgar exceed the diamond[1] in refractive power; that diamond, phosphorus, and sulphur have their high refractive powers in the order of their inflammabilities; that fluor spar and cryolite have their refractive powers below all solid substances, (excepting *tabasheer)*, and lower dispersive powers than all other bodies; and that all doubly refracting crystals have a double dispersive power. He shewed that oil of cassia had the least, and sulphuric acid the greatest action upon green light; that a tertiary spectrum is formed, when prisms of the same substance but different angles are made to correct the dispersion, by the inclination of one of them; and that achromatic combinations may be effected by prisms and lenses of the same kind of glass.

In the year 1812, he began to study the subject of the polarisation of light, in consequence of having become acquainted with Malus's celebrated discovery of the polarisation of light by reflexion. He discovered the remarkable property of the agate, by which it gives only a single distinct image polarised in one plane; the property of depolarisation possessed by almost all minerals, and by many animal and vegetable substances;[2] the polarised colours produced by thin plates of mica and topaz; the partial polarisation of light by polished metals;[3] and the complete polarisation of the exterior and interior rainbows.

In the course of these inquiries our author discovered the two beautiful systems of elliptical coloured rings, which we see by transmitting polarised light along the two optical axes of topaz; and in consequence of his using a conical in place of a parallel beam of light in these experiments, he was led to observe the same system of rings, under different modifications, in various other bodies. While examining the depolarising effect of a plate of mica at an oblique incidence, he was led to the discovery of the polarisation of light by oblique transmission through bundles of crystallised or uncrystallised plates; and though Malus had anticipated him in this discovery, yet he had determined the law of the phenomena, which had escaped the notice of that skilful observer.

Hitherto no idea had been formed of the mechanical condition of bodies in which the polarising and doubly refracting structure were exhibited; but in the years 1814 and 1815, a new light was thrown upon the subject, by three discoveries made by Sir David Brewster, namely, that the polarising structure could be produced in glass by heat, and also by rapid cooling;[4] that Prince Rupert's glass drops, formed by rapid cooling, possessed that structure;[5] and that *by means of simple pressure, that species of crystallisation could be communicated to soft and indurated jellies, which forms two apparently polarised images, and exhibits the complementary colours by polarised light.*[6]

We have already seen that Malus considered the property of polarisation by reflexion as independent of the other modes of action which bodies exercise upon light. In order to investigate this subject, Sir David Brewster made an extensive series of experiments to determine the angles of maximum polarisation by reflexion, from the surfaces of bodies, and from the separating surfaces of different media. After encountering many difficulties, he was led to the discovery of the very simple law *that the index of refraction is the tangent of the angle of polarisation*, which is rigorously true for all separating surfaces, and for rays of all refrangibilities; and hence we obtain an immediate explanation of the perplexing fact, that at the maximum polarising angle the polarisation of the ray is never complete. When this law is expressed geometrically, it informs us that when a ray of light is polarised by reflexion, the reflected ray forms a right angle with the refracted ray; that the sum of the angles of reflexion and refraction is a right angle, or counting from the surface, that the angles of reflexion and refraction are equal. In the same paper, our author has shewn that light may be completely polarised by two, three, or more reflexions, at angles all above or all below, or partly above and partly below the angle of complete polarisation, a greater number of reflexions being required, as the incident ray approaches either to the refracting surface, or to a line perpendicular to it. In the same paper, it is shewn that every ray of light polarised by reflexion has been acted upon by the refracting force; and that total reflexion exercises an analogous action upon light with metallic surfaces.

The influence of heat in producing a transient polarising structure in glass, led our author to an elaborate examination of the subject in 1815.[7] When the edge of a thick plate of glass is laid on a bar of hot iron, the heat gradually propagates itself along the plate, and its path is marked by the most beautiful fringes of polarised light; but no sooner has the heat entered the plate of glass, than similar fringes appear on its upper edge, *where there is no heat at all.* After a certain period, the whole surface of the glass is covered with coloured fringes, which are arranged in two similar polarising structures at the edges, separated by two dark lines or axes from an opposite structure in the middle. When the glass is removed from the iron, the fringes gradually disappear, and are extinguished when the heat is uniformly diffused over the glass. If the plate of glass is made very hot in boiling oil, and is then allowed to cool with its edges against a plate of cold iron, it will exhibit in a fainter degree the fringes above described; but they are now all reversed, the middle structure having the same character as the external structures had formerly, and *vice versa.* If, when a plate of glass is covered over with the polarised tints, it is suddenly cut in two by a diamond in the direction of its length, the whole structure is instantly changed, and each piece has the same properties and structure as the whole, exactly like a portion detached from the end of a magnet. The same properties he found in muriate of soda, fluor spar, obsidian, semi-opal, horn, tortoise-shell, and various animal and vegetable bodies. The tints thus developed by heat exhibit, by their being made to cross one another and by other modifications, a series of the most brilliant phenomena within the whole range of optics.

In continuing these experiments, our author found that when the plate of glass, after being brought to a red heat, was allowed to cool quickly, it exhibited permanently the same coloured fringes, a discovery which had likewise been made by Dr. Seebeck of Nuremberg.

This paper is followed by another, published in the same

[1] In all tables of refractive powers of solids and fluids, *diamond* stood at the head, and *water* and *ice* at the bottom. Our author, however, placed various substances above *diamond*, and *tabasheer* far below *ice*.

[2] *Phil. Trans.* 1815, p. 27.

[3] These discoveries were communicated to the Royal Society of Edinburgh, and owing to the state of communication between France and England, neither the author nor any of the members of the Society were acquainted with the previous discovery of M. Arago of the colours of crystalline plates, or with those of Malus on depolarisation and metallic polarisation.

History.

volume of the *Transactions*,[1] *on the communication of the structure of doubly refracting crystals, to glass, muriate of soda, fluor spar, and other substances, by mechanical compression and dilatation;* and on the 17th November 1816, our author communicated to the Royal Society of Edinburgh another paper, *on the effects of compression and dilatation in altering the polarising structure of doubly refracting crystals.*[2]

In 1816 he communicated to the Royal Society his experiments on mother-of-pearl, explaining the origin of its fine superficial colours, and shewing that they could be communicated to wax, isinglass, the fusible metals, and even to lead, by hard pressure. In 1815 he published a paper *on the multiplication of images, and the colours which accompany them, in some specimens of calcareous spar*,[3] a subject which had exercised the sagacity of Huygens, Benjamin Martin, Brougham, Robison, and Malus. The last of these philosophers ascribed the multiplication of the images to the interception of the pencils by fissures within the crystal, and the colours to the thin plate of air which it enclosed; but Sir David Brewster discovered the true cause of the phenomena, and proved that there were no fissures nor plates of air; that the multiplication of the images arise from one or more veins of calcareous spar, which divided the rhomb into prisms, so as to form composite crystals, having the axes of crystallization and of double refraction of the two contiguous crystals turned round 180°, so that each of the two pencils formed by double refraction are subdivided in passing from the one crystal to the other. He has shewn also that the colours are the polarised tints produced by thin plates crystallized, these plates giving the regular system of coloured rings seen along the axis of calcareous spar, the light being polarised by the first prism of spar, and analysed by the last. Hence it follows that the polarised tints of crystals were seen and studied by Huygens and his successors, without having any idea of what they were.

The crystalline lenses of animals had hitherto been supposed to increase regularly in density, from the circumference to the centre, for the purpose of correcting the spherical aberration. Sir David Brewster, however, shewed, in 1816,[4] that there were often *three* structures in such lenses, a structure increasing in density from the centre, being accompanied with another diminishing in density, and that these structures displayed themselves in circular rings of polarised tints, traversed by a rectangular black cross, the tints themselves sometimes rising to a bright yellow of the first order. About the same time he discovered the remarkable property of the *diamond*, of exhibiting irregular patches of doubly refracting structures, as if it had been in the state of gum, subject to irregular pressure, or induration;[5] and having afterwards discovered gaseous cavities in the same gum, in which the expansive pressure of the included gas had communicated to the surrounding parts a regular doubly refracting structure, he corroborated his supposition that it had a vegetable origin,[6] which he has more recently confirmed by discovering that many diamonds consist of strata of different refractive powers, a property not possessed by any mineral body.[7]

In the beginning of February 1815, when examining the action of metals upon polarised light, our author discovered that complementary colours were produced by one or more reflexions from plates of gold, silver, and other metals; that analogous colours were produced by total reflexion; that common light was wholly polarised in the plane of incidence by a number of metallic reflexions, this number being greater in silver and gold than in the other metals. Though examined with much care both by our author and M. Biot,[8] the nature and law of these phenomena were still veiled in obscurity.

History.

Hitherto all crystals were believed to have one axis of double refraction, like Iceland spar or quartz; but in the year 1817,[9] Sir David Brewster discovered that the greater number of crystals, and among these arragonite, sulphate of iron, sulphate of barytes, sulphate of strontian, topaz, felspar, and nitre, had *two axes* of double refraction, which he called resultant axes, and which were more or less inclined to each other, as the intensity of the real axes more or less approached to equality. By measuring the deviation of the two pencils in different planes, he found that the double refraction was the same in every part of the same ring, disappearing along the resultant axis, and increasing with the value of the tints; and by projecting the coloured rings, and measuring the angular distances from the axis at which the same tints were produced, he was led to the true physical law of the tints, and of the deviation of the extraordinary ray. This general law, when applied to the polarised tints, is thus expressed: *The tint produced at any point of the sphere, by the joint action of two axes, is equal to the diagonal of a parallelogram whose sides represent the tints produced by each axis separately, and whose angle is double of the angle formed by two planes passing through that point of the sphere and the respective axis.* When the law is applied to the phenomena of double refraction, it may be thus expressed: *The increment of the square of the velocity of the extraordinary ray produced by the action of two axes of double refraction, is equal to the diagonal of a parallelogram whose sides are the increments of the square of the velocity produced by each axis separately, and calculated by the law of Huygens, and whose angle is double of the angle formed by two planes passing through the ray and the respective axis.* When the two rectangular axes are of equal intensity and of the same character, the preceding law gives the very same results as the law of Huygens does for one axis placed at right angles with the other two. When the crystal has three equal rectangular axes, their forces are in equilibrio in every part of the sphere, and there is neither double refraction nor polarisation. When the first of these laws is applied to the mysterious actions of sulphate of lime, with the origin and classification of which M. Biot had been so much perplexed, and which he has represented by complicated and empirical formulæ, the whole mystery disappears, and *all* the diversified and capricious variations of tint which he had ascribed to secondary forces, become the legitimate and calculable results of two axes of double refraction.

During these laborious researches, our author was led to the law by which the primitive forms of minerals are connected with the number of their axes of double refraction, and to point out the connexion between the optical structure and chemical composition of crystals.

The absorption of common light, in virtue of which crystals exhibit different colours, or shades of colour, in different directions, had been long observed by Wollaston, Cordier, Bournon, De Drée, and others; but Sir David Brewster discovered that in a great number of coloured crystals, both with one and two axes of double refraction, polarised light was absorbed, according to regular laws depending on the inclination of the ray to the axis or axes of the crystal, and that in such crystals the two pencils are always differently coloured, the difference of colour disappearing in the direction of the axis, and rising to a maximum at right angles to it. These phenomena are finely seen in super-acetate of

History.

copper, dichroite, Brazilian topaz, and augite. These properties are shewn by our author to be singularly modified by heat, and even communicated to crystals which do not naturally possess it. Absorbing crystals have been called *dichroitic*, and the property itself *dichroism*.

The subject of circular polarisation was likewise examined by our author in quartz and amethyst.[1] He found that heat entirely removed from quartz the power of producing circular polarisation, when the substance was reduced to fusion; he discovered it near the resultant axis of chrysoberyl, and in certain specimens of unannealed glass.[2] In examining the proportions of the amethyst, he found that this interesting mineral combines the opposite structures of the two kinds of quartz, being composed of alternate strata of right and left-handed quartz, these two opposite actions destroying each other at their junction, where the colouring matter of the amethyst is principally apparent.

In all the experiments on the polarisation of light by reflexion from crystallised surfaces, their action was supposed to be the same as that of common solids and fluids, and Malus had distinctly stated it as the result of experiment, that Iceland spar had the same polarising angle on all its surfaces and in every azimuth, its action being "independent of the position of the principal sections," "that its reflecting power extends beyond the limit of the polarising forces of the crystal, and that as light is only polarised by penetrating the surface, the force which produces extraordinary refraction begins to act only at this limit."[3] Doubting the accuracy of these results, Sir David Brewster instituted a series of experiments *on the action of crystallised surfaces upon light*, by which he has established the remarkable fact that the angle of complete polarisation varies from 57° 14′ to 59° 32′, on the surface of the rhomb of calcareous spar, being a minimum in the plane of the principal section, and a maximum in a plane perpendicular to it. But it is not merely the polarising angle that is changed. When the ordinary reflecting force is weakened by causing the reflexion to be made from the refracting surface of oil of cassia and Iceland spar, he found that the light was no longer polarised in the plane of reflexion, and that the deviation from this plane depended on the inclination of the ray to the axis of the crystal, the deviation becoming less and less as the refractive power of the fluid was diminished. In the same paper he has shewn that by altering the mechanical condition of the surfaces of crystals, and making the ray enter this surface from fluids of different refractive powers, the ordinary or the extraordinary image may be weakened or extinguished at pleasure.[4]

In the year 1816, Sir David Brewster discovered a remarkable system of coloured rings in apophyllite, a singularly constituted crystal, one part of which has one axis, whilst another part has two axes of double refraction. Different parts of this crystal possess different degrees of double refraction, with the same thickness, and at the same inclination to the axis; and the beautiful and symmetrical figure which a perfect crystal exhibits by polarised light, delineated in the most splendid colours, is perhaps the finest sight which the mineral kingdom can present to us.[5] By the aid of polarised light, our author discovered also a singular structure in certain crystals of chabasie, in which the double refraction gradually diminishes in successive strata, then vanishes, and reappears with an opposite sign, the one double refraction being positive and the other negative; but the most remarkable of all these structures was that of *analcime*, in which he discovered a new species of double refraction, in which the phenomena are related to planes in place of axes, in which the double refraction disappears.[6]

In the year 1829, our author communicated to the Royal Society of London six papers. The first of these was *on the reflection and decomposition of light at the separating surfaces of media of the same and of different refractive powers*.[7] The second, entitled, *on periodical colours produced by the grooved surfaces of metallic and transparent bodies*,[8] contains an account of a new series of periodical colours exhibited by grooved surfaces, which succeed each other in a plane at right angles to that in which the usual spectra are seen, and producing a singular modification of these spectra; phenomena not yet brought within the pale of the undulatory theory. In the third paper, *on the double refraction produced by pressure in the molecules of bodies*,[9] he has shewn that the axis of pressure is a regular axis of double refraction, and that the doubly refracting properties, which are not inherent in the molecules themselves, are produced by the pressure caused by the forces of aggregation, which generally differ in intensity in the direction of the three rectangular axes. The same author has more recently succeeded in producing regular double refraction by the expansive presence of heat. The other three papers treat of the laws of the polarisation of light by reflexion[10] and refraction,[11] and on the action of the second surfaces of transparent plates[12] upon light. In these papers he has given formulæ for computing the quantities of light polarised at all incidences, both by reflexion and transmission; and has explained all the phenomena of partial polarisation, and those produced by any number of successive reflexions and transmissions. In the last of these three papers our author shews that the quantity of polarised light in the light reflected and transmitted by a transparent plate is not equal at all angles of incidence, and that the proposition is true when applied to surfaces alone, the apparent equality in the first case being produced by unexcluded light polarised perpendicular to the plane of reflexion.

We have already seen that Malus, Biot, and Sir David Brewster had been baffled in their attempts to unravel the complex phenomena of metallic polarisation. The last of these authors had at various times resumed the investigation; but it was not till February 1830, that he communicated the result to the Royal Society, in a paper entitled, *on the phenomena and laws of elliptic polarisation, as exhibited in the action of metals upon light*.[13] All the phenomena of metallic polarisation are shewn to be those of elliptical polarisation, connecting the phenomena of circularly polarised light with those of plane polarised light, the action of *silver* approaching nearest to that of totally reflecting surfaces by which circular polarisation is produced, and that of *galæna* to transparent bodies or those not metallic, by which plane polarisation is produced. The colours accompanying these phenomena have no relation to those of crystallised plates, and in the case of silver and gold are extremely beautiful and splendid.

Hitherto the analysis of solar light by Sir Isaac Newton had been regarded as complete, and incapable of any farther development. From this analysis he himself deduced the conclusion, *that to the same degree of refrangibility ever belonged the same colour*, and to the same colour ever belonged the *same degree of refrangibility*. So early as 1822, in a paper, on the *monochromatic lamp*, &c.,[14] Sir David Brewster shewed that some of the colours of the spectrum

History.

were *compound*, capable of being analysed by absorbing media, and that *different colours had the same refrangibility*. This result stood in direct opposition to the Newtonian doctrine, and our author, in order to support it, undertook an elaborate series of experiments the results of which were communicated to the Royal Society of Edinburgh in 1831, in a paper entitled, *on a new analysis of solar light*, indicating *three primary colours forming coincident spectra of equal lengths*.[1] In these three overlapping spectra the intensity of each colour is a maximum at that point where the same colour is most intense in the compound spectrum. Hence it follows that all the colours in the solar spectrum are compound, consisting of red, yellow, and blue light in different proportions, so that if at any point we separate as many rays of each colour as is necessary to produce *white* light, by absorbing the excess at that point, we should exhibit the strange phenomenon of *white light incapable of being decomposed by the prism*. This has actually been done by Sir David Brewster, by means of absorbing media. But in a very recent communication made to the Royal Society, (in June 1837), he has explained a new method of effecting this by perfectly transparent media, which he calls *analysis by dissection*, and of which we shall give some account in another part of this article. This paper was followed, in 1833, by another, *on the colours of natural bodies*,[2] in which our author shews that they have not the same composition as those of thin plates, and demonstrates the truth of this opinion by a special analysis of the green colour of plants, the most prevalent tint in nature, and the one which Newton had pronounced to be of the third order. In the same year our author published his *Observations on the Lines of the Solar Spectrum, and on those produced by the earth's atmosphere, and by the action of nitrous acid gas*,[3] but we must reserve our notice of this paper till we come to describe the discoveries of Fraunhofer.

Dr. Seebeck. Born 1770. Died 1831.

The late Dr. Thomas John Seebeck of Nuremberg, was an active and successful cultivator of the science of Optics. His first experiments on this subject were published in Schweigger's Journal for April 1813 and December 1814. In 1811 M. Arago observed the polarising structure in thick pieces of flint, and in 1812 Sir David Brewster had noticed the same property in some pieces of plate glass.[4] In Dr. Seebeck's paper of 1813, he observed the regular figure produced by polarised light, when the glass had the regular form of cubes and cylinders. In cubes of an inch in diameter, he found them to be indistinct, and not produced by fluor spar or rock salt. In his second paper of December 1814, he shews that a plate of glass made red hot, and set upon its edges to cool, exhibits at the part which cools first a series of coloured fringes, which spread over the whole plate, the structure which produces them remaining permanently fixed in the glass. These experiments are posterior to those made in Scotland on the effects of heat upon glass, and on the polarising structure of glass cooled in water.

Early in 1816, Dr. Seebeck discovered the property of certain essential oils in producing the polarised tints, the property of single refraction possessed by tourmaline, and the system of coloured rings produced by Iceland spar; but in these discoveries he was anticipated, as we have seen, by others, though he is entitled to all the merit of a second discoverer.

In 1809 Dr. Seebeck communicated to the Academy of Sciences at Berlin, an interesting memoir *on the unequal production of heat in the prismatic spectrum*,[5] in which he shewed that the place of maximum heat varied with the substance of which the prism was made, being in the *yellow rays* in the spectra formed by water, (and according to Wunsch, in alcohol and oil of turpentine); in the *orange* in concentrated sulphuric acid, and solution of sal ammoniac and corrosive sublimate; in the *middle of the red* in crown and plate glass, and *beyond* the red in flint glass. Dr. Turner[6] ascribed these results to the different powers of these media to refract the rays of solar heat; but Sir David Brewster explained them by supposing that colourless transparent bodies exercise the same variety of absorptive action upon heat that coloured bodies do upon light, the body in the last case becoming coloured in consequence of that action. Hence the maximum ordinate of heat will shift its position with the nature of the body, and we shall no doubt find media, several maxima and minima, and points of no heat at all, according as we increase the size of the prism or the thickness which the heat traverses.[7] The best way to carry such researches is to use a prism of glass whose curve of heat is well ascertained, and then to determine the changes which take place in the curve by interposing thick plates of transparent solids and fluids.

This eminent philosopher would have done still more for the science of optics, had he not been attracted to the study of thermo-electricity, in the creation and extension of which he has immortalised his name.

Dr. Seebeck.

We are indebted to Dr. A. Seebeck for a series of instructive and accurate experiments on the polarising angle of different substances, which confirm the accuracy of the law of the tangents,[8] and another on the polarising angle of calcareous spar in different azimuths.

Fresnel. Born 1788. Died 1827.

We come now to that auspicious period in the history of optics, when this science was destined to receive the grandest accessions from the genius of M. A. Fresnel, engineer of roads and bridges. What Newton did for astronomy, Fresnel did for physical optics; and all Europe will, we are persuaded, confirm the decision which places him pre-eminently above all the other cultivators of this branch of science. The discoveries of Fresnel, however, are so connected with theoretical considerations, that it is impossible, in a historical sketch, to give any thing like an idea of their magnitude and importance. The phenomena of rotatory polarisation in quartz, which had so much perplexed philosophers, have been completely explained by Fresnel. He found that they arise from the interference of two circularly polarised pencils, propagated with different velocities along the axis of quartz, the one revolving from right to left, and the other from left to right, and that a plane polarised ray is equivalent to two circularly polarised rays of half the intensity. These facts he verified experimentally, by an achromatic combination of right and left-handed prisms of quartz, so disposed as to double the refraction of the images.

M. Fresnel had also found that light was circularly polarised by two total reflexions from glass at an angle of about 54° 37′, and by placing between two rhombs of glass, each of which polarised the light circularly and had their planes of reflexion at right angles to each other, a crystallised plate, he observed the light transmitted through this system exhibited phenomena analogous to those seen along the axis of rock crystal. The rhomb of glass so cut, that when the incident rays enter and leave it perpendicularly, they have suffered two reflexions at an angle of 54° 37′, is well known by the name of Fresnel's rhomb.

Fresnel's theory of double refraction and polarisation, one of the finest efforts of genius, conducted its author to many important results which had escaped the notice of the most diligent observers. Hitherto it had been taken for granted by all, and appeared to be proved by Biot's experiments on topaz, that in biaxal crystals one of the rays

followed the ordinary law of the sines; but it followed from Fresnel's theory that it did not, and by a series of the nicest and most difficult experiments he determined, that neither of the two rays have a constant velocity, both being performed according to a new law. What had been called the extraordinary ray, he found by his theory to be regulated by the law discovered by Sir David Brewster, and simplified in its mathematical expression by M. Biot, and he shewed that all the phenomena of double refraction could be accurately calculated. The axes of elasticity in Fresnel's theory are the same as the axes of double refraction in Sir David Brewster's, and the laws of the composition and resolution of such axes in uniaxal, biaxal, and tessular crystals, which have no double refraction previously given by the latter, are all necessary results of the same theory.

But the most remarkable part of Fresnel's theory is his explanation of the polarisation of light. The hypothesis of *transversal vibrations* first presented itself to Dr. Young while considering the law of extraordinary refraction in biaxal crystals, as communicated to him by Sir David Brewster. M. Fresnel, however, shewed that it was a necessary consequence of the laws of interference, and that the vibrations of a polarised ray are on the surface of the wave, and perpendicular to the plane of polarisation. In unpolarised light they are also only on the surface of the wave, and this species of light is conceived to "consist of a rapid succession of systems of waves polarised in every possible plane, passing through the normal to the front of the wave." Hence light is polarised by resolving the vibrations into two sets in two rectangular directions.[1]

We have already slightly noticed the fine discoveries of MM. Arago and Fresnel on the interference of polarised light, and we can now only refer with admiration to the beautiful series of experiments by which the phenomena of moveable polarisation were properly explained, and brought under the dominion of the undulatory theory. When a polarised ray proceeding from a luminous point was transmitted through two rhomboids of Iceland spar of equal thickness, whose principal sections were inclined 45° to the plane of primitive polarisation, the emergent light will diverge as if from two near points, and the two portions will be oppositely polarised. MM. Arago and Fresnel found that the light formed by the union of these pencils was *plane*, *circularly*, or *elliptically* polarised, according to the difference of the paths traversed when they met. Following out this principle, MM. Arago and Fresnel were led to an *experimentum crucis*, to determine the accuracy of the theory of moveable polarisation. A homogeneous ray of polarised light was transmitted through a plate of sulphate of lime, having its principal section inclined 45° to the plane of primitive polarisation, and of such a thickness that it should be circularly polarised according to the undulatory theory, and plane polarised according to the other; and the result was decisive against the theory of moveable polarisation.

We owe also to M. Fresnel the true theory of the inflexion or diffraction of light. The Institute of France made this the subject of their physical prize for 1818, and the memoir of our author was the successful one. He had at first adopted and extended the theory of Dr. Young, that the fringes arise from the interference of the direct and inflected light; but he was afterwards obliged to admit, that rays passing at a sensible distance from the reflecting body, deviate from their primitive direction, and interfere with the direct light. This interesting effect he ascribes to a number of elementary waves sent from each portion of the surface of the principal wave when it reaches the reflecting body, and he determines the resultant of all the elementary waves sent by these portions to a given point. Upon applying this theory to various cases of inflexion, he found it to agree so well with observation, that, with the exception of the case of diffraction by narrow apertures, the theory did not err more than the 2500th part of an inch.

Among the many important discoveries of Fresnel we must enumerate the theory of the reflexion of light. Dr. Young had shewn on the undulatory theory, that at a perpendicular incidence the intensity of the reflected light was a very simple function of the index of refraction.[2] M. Poisson had arrived by another process at the same result, without knowing, we believe, what had been done by Dr. Young;[3] and he afterwards extended his inquiries to different incidences.[4] The conclusions, however, at which this distinguished mathematician arrived, were inconsistent with observation; and Fresnel had the good fortune to give a complete solution of the problem, by combining the doctrine of transversal vibrations with the theory of waves. He assumes, that the elasticity of the ether in the two media are equal, but their density different, though he also solved the problem on the more general assumption, that the elasticity was different in the two media. He thus obtained formulæ for all incidences and all refractive powers, and the law of the tangents, as well as that of the equality of pencils, polarised by reflexion and transmission, became the consequences of these formulæ. At a perpendicular incidence the formula coincides with that of Young and Poisson, and at 90° the whole light is reflected, a result which has been verified by observation.[5]

Fraunhofer Born 1787. Died 1826.

Contemporary with the discoveries of Fresnel were those of the late M. Fraunhofer of Munich, who made several important observations on the solar spectrum, on the diffraction of light, on refractive and dispersive powers, and on the refrangibility of the light of the fixed stars. By using fine prisms entirely free of veins, he discovered that the solar spectrum was crossed by about 590 black lines, and he executed a beautiful drawing of the spectrum, in which the most important of these are projected. Fraunhofer was not aware that Dr. Wollaston had previously discovered *seven* of these lines; but this slight anticipation does not in the least degree diminish the singularity of this splendid discovery. He discovered similar lines in electric light, and in the spectra of the Moon, Venus, Mars, Castor, Pollux, Sirius, Capella, Betalgeus, and Procyon;[6] but none whatever in artificial white flames. These lines he found to have a fixed position in relation to the coloured spaces, and, by measuring accurately the distance of prominent lines in the different coloured spaces, he obtained measures of the refractive and dispersive powers of bodies with a degree of accuracy hitherto unknown. Fraunhofer considered these lines as having their origin in the nature of the sun's light; but Sir David Brewster, who by particular methods has discovered more than twice the number of lines reckoned by Fraunhofer, has established the curious fact, that many of them are produced also by the action of the earth's atmosphere. In his researches on this subject Sir David Brewster discovered the remarkable property possessed by nitrous gas of producing analogous lines in great numbers, increasing in width with the thickness of the gas, or with an augmentation of its temperature. "The power of heat alone," says this author, "to render a gas, which is almost colourless, as red as blood, without decomposing it, is in itself a most singular result; and my surprise was greatly

History.

increased, when I afterwards succeeded in rendering the same pale nitrous acid gas so absolutely black by heat, that not a ray of the brightest summer sun was capable of penetrating it."[1] Professors Miller and Daniel afterwards discovered numerous fixed lines disposed at equal distances, in the vapour of bromine and iodine, and Sir David Brewster has very recently discovered hundreds of lines under very singular circumstances, in the spectrum of an artificial substance, resembling mother-of-pearl;[2] but what is most interesting, these lines are *moveable*, *shifting their place in the spectrum by varying the incidence*, and are produced by the periodical action of *thin plates* enclosed in the substance. He has also discovered, that broad dark bands like those produced by absorbing media, but entirely different from the nearly equidistant bands formed by single thin plates, are produced by a number of thin plates in a state of combination.[3]

Considering the lines of the spectrum as produced by interference, Fraunhofer was induced to make a complete series of experiments on the *inflexion of light*, particularly on the splendid colours produced by gratings of wires, and grooved surfaces, which were published in the year 1822, in the *Memoirs of the Royal Bavarian Academy of Sciences*.[4] He afterwards repeated these experiments with a finer apparatus, and communicated an account of them to the Academy of Sciences at Munich, on the 14th June 1823.[5] The science of optics owes also to Fraunhofer the art of making the finest glass for achromatic telescopes and prisms, and such was the perfection at which he arrived, that, in a letter to the author of this article, he expresses his willingness to undertake an achromatic object glass *eighteen inches in diameter*. Our author wrote also a treatise on halos, parhelia, &c., in which he ascribes the small solar and lunar halos to the inflexion of light, by particles of vapour in the atmosphere, and the great halos of 45° to the refraction of hexagonal prisms of ice.[6]

Sir John Herschel.

Among the most distinguished contributors to optical discovery, Sir John Herschel occupies a high place. The deviations of the polarised tints from the colours of thin plates, or those of Newton's scale, had been discovered by Sir David Brewster in acetate of lead, tartrate of potash and soda, apophyllite, topaz, and various other minerals. He had divided these crystals into two classes, viz. those that had the *red* ends of the rings *inwards*, and the *blue* ends *outwards;* and those that had the *blue* ends of the rings *inwards*, and the *red* ends *outwards*.[7] In his paper of 1818, he states, that "in almost all crystals with two axes, the tints in the neighbourhood of the resultant axes, when the plate has a considerable thickness, lose their resemblance to those of Newton's scale, as will be more minutely described in another paper." Conceiving that these deviated tints arose from the superposition of systems of rings of different colours, Sir John Herschel examined the coloured rings by homogeneous light, and established the important fact that the inclination of the resultant axes varied in the different colours of the spectrum, the poles or centres of the rings approaching to each other in red, and receding in violet light, in some crystals; while in others they receded from each other in red, and approached in violet light. In tartrate of potash and soda, for example, the inclination of the axes was 75° 42′ in *red*, and only 55° 14′ in *violet* light.[8] These various axes all lie in the same plane, excepting in borax. In the paper containing this discovery, and in other two,[9] communicated to the Cambridge Philosophical Society, he has described various interesting phenomena which he discovered in different specimens of apophyllite and in hyposulphate of lime,[10] and which led him to some interesting conclusions respecting the law of proportional action of these crystals on the different colours of the spectrum.

We have already seen that the force which produces circular polarisation had been deemed a property of the ultimate particles of bodies, and totally unconnected with their mode of aggregation. In 1820 Sir John Herschel made the beautiful discovery, that the direction of the circular polarisation in quartz was invariably the same with that of the plagiedral planes round the summit, the direction of the polarisation being retrograde or direct, according as these planes leant forward or backward round this summit.

We owe also to Sir John Herschel an interesting inquiry into the *aberrations of compound lenses and object-glasses*,[11] a series of curious experiments on the phenomena produced by diaphragens or apertures of various shapes, variously applied to mirrors and object-glasses,[12] and a great number of original views and valuable experiments, which are contained in his *Treatise on Light*, one of the most valuable and original works on science which has appeared during the last century.

M. Mitscherlich.

M. Fresnel was, we believe, the first person who observed the change produced by heat on the tints of sulphate of lime. It is to M. Mitscherlich, however, that we owe the most complete investigation of this subject. He found that heat expands crystals differently in different directions. Iceland spar is expanded by it in the direction of its axis, while it is in a slight degree contracted in directions perpendicular to the axis. The rhomb thus approaches to the cube, and the double refraction is diminished. M. Mitscherlich also found that the inclination of the optical or resultant axes, which is about 60°, diminishes with heat till they actually form one axis, when by a farther increase of heat they again separate, and open out, as it were, in a plane at right angles to that of the laminæ. We have repeated this experiment, and enjoyed the remarkable sight of observing the one system of rings marching towards the other in the plane of the laminæ, and changing their form and size as they advanced.[13] An analogous, and even a more remarkable property, was discovered by Sir David Brewster in glauberite. At the freezing point glauberite has two optical axes for all the colours of the spectrum, the inclination of the axes being *greatest* in *red*, and *least* in *violet* light. When heat is applied, the two axes approach, and those of different colours unite successively, the crystal possessing the remarkable property of being a *uniaxal* one for *red*, and a *biaxal* one for *violet* light. By increasing the temperature, the optical axes open out in the same order, but in a plane at right angles to that in which they formerly lay, and long before the temperature has reached that of boiling water the planes of the axes in all the prismatic colours are perpendicular to their first position.[14] Such a crystal would form a delicate chromatic thermometer.[15] M. Marx has discovered an analogous property in topaz, in which the two axes separate with heat, the variation being greater in the coloured than in the colourless varieties.[16] Sir David Brewster has discovered that regular double refraction is produced in some soft substances by the application of heat.

M. Rudberg.

Some very excellent and interesting results have been obtained by M. Rudberg, on the effect of heat upon doubly

refracting crystals. He found that the extraordinary ray in calcareous spar (the line F was used) had its deviation increased 2′ 34″, as the refractive index increased 0·00043, by a rise of temperature equal to 64°, the refracting angle of the prism being 59° 55′ 9″, whereas the refractive power for the ordinary ray either does not change at all, or decreases with the temperature by a quantity extremely small. In rock crystal he found the deviation to be 42″, or 0·00027, both on the ordinary and extraordinary ray, the angle of the prism being 45° 20′ 5″. In arragonite he found that the double refraction decreased a little with the temperature.[1]

We owe also to M. Rudberg a series of valuable experiments on the refractive actions of the differently coloured rays in crystals with one and two axes of double refraction. His measures were taken in reference to the fixed lines in the spectrum, and the minerals he employed were rock crystal, calcareous spar, arragonite, and colourless topaz. He confirmed the existence of two dispersive powers in doubly refracting crystals, announced long before by Sir David Brewster; and the variation of the inclination of the optic axes with the different colours of the spectrum, which had also been previously discovered by Sir John Herschel.[2] M. Rudberg was no doubt unacquainted with the previous labours of these authors, otherwise he would not have passed them over without notice.

M. P- son. Born .81.

Like every other branch of physical science, optics owes much to the profound researches of M. Poisson, which are in general of too recondite a nature to find a place in a popular treatise. The theory of the colours of thin plates was left incomplete by Dr. Young. The two interfering portions from the upper and under surface of the plate were obviously unequal, and therefore could not destroy one another wholly by interference, as they are found to do. M. Poisson remedied this defect by shewing that there must be an infinite number of partial reflexions within the plate, at each of which a very small portion of light was reflected, so that the sum of all these portions of light makes up for the defect of one of the pencils, and makes the interfering pencils equal. Hence M. Poisson has shewn that at a perpendicular incidence, and at points where the effective thickness of the plate is an exact multiple of the length of half an undulation, the intensity of the reflected and transmitted light will be the same as if the plate were suppressed altogether, and the bounding media in absolute contact, so that when these media have the same refractive power, no light will be reflected and the whole transmitted. By the aid of the property discovered by M. Arago, that the light is reflected in the same proportion at the first and second surfaces of a plate, M. Fresnel extended M. Poisson's conclusions to all incidences.

In treating of the subject of diffraction, M. Poisson was led to the curious result that the centre of the shadow of a small opaque circular disc, exposed to light diverging from a single point, is as much illuminated by the diffracted light as it would be by the direct light, if the opaque disc were removed. By cementing a small metallic disc upon a plate of pure and homogeneous glass, M. Arago verified this remarkable deduction of theory.

M. Poisson's researches on the propagation of motion in elastic fluids, and their application to light, are too profound to admit of a brief and intelligible analysis.

Ampèr Born 1 5.

In two memoirs read to the Academy of Sciences in 1828,[3] M. Ampère has made a valuable addition to the theory of Fresnel. By an indirect and not very rigorous process, M. Fresnel had been led to the equation of the wave surface;[4] but M. Ampere obtained a direct demonstration of it, deducing the equation in the manner which Fresnel had merely indicated, and he derived from this equation the elegant geometrical construction obtained indirectly by Fresnel.

History.

M. Cauchy.

The undulatory theory of light has been greatly advanced by the researches of M. Cauchy, a French mathematician of distinguished eminence. In determining the law of propagation of a plane wave, he shews that a disturbance originally limited to a given plane will give rise to three pairs of plane waves with uniform velocities, and parallel to the original plane, the two waves of each pair moving in opposite directions, but with equal velocities. He shews that the separate pairs will move with velocities represented by the reciprocals of the axes of an ellipsoid, the form of which is regulated by the position of the plane wave, and the nature of the system, the absolute displacement of the molecules being parallel to the direction of these axes. Hence a system of plane waves superposed at the point of original disturbance, will be divided into three corresponding systems, and these will generate by their superposition a curved surface of three sheets, each sheet being touched by all the plane waves of the system. If these principles are established, it will follow as a necessary consequence *that a single ray of light will be divided into three polarised rays*, one of which will in all cases have little intensity. M. Cauchy, as Professor Lloyd[5] remarks, has not pointed out the method of discovering this ray, or stated the precise physical condition on which its existence depends; but it "would seem to arise from the circumstance that the vibration normal to the wave is not absolutely insensible, so that the actual vibrations are not accurately in the plane of the wave."[6] "The results of M. Cauchy's general theory," continues Professor Lloyd, "embrace and confirm those of Fresnel; and the mathematical laws of the propagation of light are shewn to be particular cases of the more general laws of the propagation of vibratory motion in any elastic medium composed of attracting and repelling molecules. Considered, however, simply with reference to the theory of light, the solution given by M. Cauchy cannot, I conceive, be considered as a complete *physical* solution. In other words, the phenomena of light are not connected *directly* with any given physical hypothesis; but are shewn to be comprehended in the results of the general theory, in virtue of *certain assumed relations* among the constants which that theory involves. If, indeed, we were able to assign the precise physical meaning of these equations of condition, we should have nothing more to desire in the general theory of light; for these equations must necessarily express the characteristic properties of the vibrating medium. In this point of view, their discussion becomes a subject of the highest interest; and it is probable that the important conclusions of which we have yet to speak, may in this manner be confirmed and extended."

Triple refraction.

Before quitting this subject, however, we ought to mention that there is an essential difference between the theories of Fresnel and Cauchy. In the former a ray is said to be polarised in or parallel to any plane, when the vibrations of the molecules of ether are *perpendicular* to that line or plane; whereas, in Cauchy's theory, a ray is said to be polarised in or parallel to any plane, when the vibrations of the ether are performed in a parallel to that plane.

Dispersion of light.

The inability of the undulatory theory to explain the dispersion of light, was long one of the few exceptions to its universal application. Dr. Young supposed that the material particles of bodies are incapable of permanent vibrations; that these vibrations will retard those of the ether; and that this retardation will be proportional to their frequency. The Rev. Mr. Challis, adopting Dr. Young's idea, has endeavoured to explain the manner in which the undulations of

History. the ether within bodies are modified by their material atoms. He supposes that a sensible reflexion takes place at every interruption of continuity in the medium; and he infers that the mean effect produced by a retarding cause proportional to the reflective power of the atoms, will be to make the condensation corresponding to a given velocity greater in a certain proportion than in free space, and to diminish the velocity of propagation in the same proportion. Mr. Airy has more recently endeavoured to remove this difficulty, by supposing that in refracting media there may be something depending on time which alters their elasticity, in the same manner as in air the elasticity is greater with a quick than with a slow vibration of particles.

An anonymous writer in a very recent number of *The Philosophical Magazine*, has proposed another hypothesis for obtaining a difference of elasticity. He supposes that the ether accumulates itself round the particles of transparent media, and forms spheres of a density increasing towards their centres; and he infers that a succession of vibrations communicated through a medium thus constituted will give rise to new vibrations propagated with various velocities corresponding to those of the different rays in the spectrum.

The complete removal of this difficulty from the undulatory theory has been effected by the skill of M. Cauchy. Regarding the sphere of action of the ethereal molecules as indefinitely small, in comparison with the length of an undulation, it had been inferred that the velocity of the undulations must be constant in the same medium; but this restriction being removed as a groundless one, M. Cauchy has considered the problem in a more general manner, and has arrived at the result, that there exists a general relation between the length of the undulations and the velocity with which they are propagated, or the index of refraction; and consequently that rays of different colours will have different degrees of refrangibility. This relation is expressed by an equation involving two arbitrary constants, depending on the nature of the medium, and determinable by two values of the index of refraction for two waves of a known length. The refractive index for waves of other lengths may then be computed. Professor Powell has done this for several media,[1] whose refractive indices for the fixed lines in the spectrum have been determined by Fraunhofer, Rudberg, and himself; but though there is a general coincidence with the theory, the differences are in some cases rather inauspicious.

M. Cauchy has more recently deduced from his general theory the remarkable fact, that in a particular case of reflexion the reflected pencil exceeds the incident one in intensity, a result which has been confirmed by direct experiment.

Mr. Airy. In examining the two rays produced by the double refraction of quartz, Mr. Airy was led to a discovery which we consider as one of the most important in its results, and one of the most beautiful in its phenomena, that has yet been made in this branch of optics. The circular polarisation of the two rays along the axis of quartz had been studied by different philosophers, and had been explained by Fresnel with singular ingenuity, on the principles of the undulatory theory. No attempt, however, had been made to account for the existence of this property only in the rays which pass near the axis of the crystal, or to define the limit where the circular polarisation ended, and the plane polarisation commenced. Fresnel, and all who have written on the subject, seem to have shrunk from this difficulty; but Mr. Airy thought that the two kinds of polarisation must have some connecting link, and by the aid of theory and experiment he succeeded in discovering it. In place of the two rays in quartz consisting of plane polarised light, as was universally believed, Mr. Airy has shewn that they both consist of elliptically polarised light, the greater axis of the ellipse for the one ray being in the principal plane of the crystal, and the greater axis of the other perpendicular to that plane. One of the rays he found to be right-handed elliptically polarised, and the other left-handed elliptically polarised. The proportion of the axes of the ordinary ray is more nearly one of equality than the proportion of the axes of the extraordinary ray, each proportion being one of equality when the direction of the ray coincides with the axis, and becoming more unequal with the inclination, according to a law not yet discovered. The results calculated from the theory are in perfect accordance with those which Mr. Airy has obtained from very nice and difficult experiments; so that we may regard this beautiful and singular property of the two rays of quartz as perfectly established.

Without knowing of the beautiful experiments of M. Arago, already referred to, Mr. Airy was led to make the same experiment on the coloured rings formed between a lens and a metallic reflector, and to draw the same conclusion from it in favour of the undulatory theory. From a consideration of the formulæ of Fresnel, Mr. Airy was led to expect that if the rings were formed between two substances of different refractive powers, such as plate glass and diamond, the light being polarised perpendicular to the plane of incidence, they should have a black centre at incidences less than the polarising angle of the glass, and greater than the polarising angle of the diamond; while they should have a white centre at all intermediate angles. These anticipations Mr. Airy confirmed by experiment; and in the course of his observations he observed certain peculiarities in the phenomena, from which he has drawn the following conclusions, viz.

1. When the angle of incidence is less than the maximum polarising angle of the diamond, the nature of its reflexion is similar to that of metallic reflexion; the phase of vibration in the plane of reflexion being more retarded than that of vibrations perpendicular to the plane of reflexion, but perhaps by a smaller quantity than in reflexion from metals.

2. In the neighbourhood of the polarising angle, the nature of the reflexion is different from any that has hitherto been described. The vibrations in the plane of reflexion do not vanish, but on increasing the angle of incidence by three or four degrees, the phase of vibration is gradually retarded by about 180°. In the reflexion of light whose vibrations are perpendicular to the plane of reflexion, there is no striking difference between the effects of diamond and those of glass.

3. For angles of incidence greater than the polarising angle, there is no sensible difference between the effects of diamond and those of glass.[2]

It would be desirable to ascertain if the diamond used by Professor Airy consisted of strata of different reflective and refractive powers, a structure lately discovered in some specimens by Sir David Brewster;[3] or if it was a heterogeneous crystal, containing particles of different degrees of density and double refraction, a structure very common in this gem.[4]

Sir W. Hamilton. Hitherto the mathematical theory of light owed almost all its development to the distinguished members of the Institute of France—to Malus, Arago, Fresnel, Poisson, Ampere, and Cauchy; but it was now destined to receive a powerful impetus from those eminent members of Trinity College, Dublin, who have nobly sustained the honour of their country by their genius and discoveries. In his *Essay on the Theory of Systems of Rays*, Sir William Hamilton has given an elegant analytical form to that part of the theory of Fresnel which relates to the determination of the velocity and polarisation of a plane wave; and he has de-

[1] *Phil. Trans.* 1835–37.

duced the velocity and direction of the ray from that of the wave, and consequently the form of the wave surface.[1] In these researches Sir W. Hamilton was conducted to the discovery of some new geometrical properties of the wave surface. He found that this surface has four conoidal cusps at the extremities of the resultant or optical axes, at each of which the wave is touched by an infinite number of tangent planes, forming a tangent cone of the second degree, while at the extremities of the lines of single wave velocity, there are four circles of plane contact, in every part of each of which the wave surface is touched by a single plane. These cusps and circles, the existence of which does not seem to have been suspected by Fresnel, have led Sir W. Hamilton to some remarkable theoretical conclusions respecting the laws of refraction in biaxal crystals. To this new property he has given the name of conical refraction, because a single ray is refracted into an infinite number, forming a kind of cone. This conical refraction is of two kinds, external and internal. In external conical refraction, one internal cusp ray corresponds to an external cone of rays; and in internal conical refraction, an external ray incident at an angle corresponding to the line of single wave velocity within, is connected with an internal cone of rays.[2]

Professor Lloyd.

Sir W. Hamilton requested Professor Lloyd, of Trinity College, Dublin, to inquire experimentally into the existence of these two kinds of conical refraction. For this purpose he selected arragonite, a crystal of great biaxal energy, and having its optic axes inclined about 20°. It was cut with parallel faces perpendicular to the line bisecting the two optic axes. Upon looking at the light of a distant lamp through the crystal, and in the direction of one of the optical axes, Professor Lloyd saw a point more luminous than the space immediately about it, and surrounded by something resembling a stellar radiation. Hence the direction of the optical axes may be determined by this modification of common light. When the adjustment was perfected, and the light transmitted in the exact direction of the cusp ray, there appeared at first a luminous circle, with a small dark space in the centre, and in this dark central space were two bright points, separated by a narrow and well-defined dark line. These appearances rapidly changed in shifting the minute aperture next the eye. On examining the emergent cone with a plate of tourmaline, Professor Lloyd was surprised to observe that only one radius of the circular section vanished in a given position of the tourmaline, and that the vanished ray ranged through 360°, while the tourmaline was turned through 180°. Hence it follows that all the rays of the cone are polarised in different planes. On a more attentive examination of this phenomenon, Professor Lloyd discovered the remarkable law, "that the angles between the planes of polarisation of any two rays of the cone is half the angles between the plane containing the rays themselves and the axis." This law he found to be in perfect accordance with the theory.

The verification of the second kind of conical refraction Professor Lloyd found to be more difficult. The angle of the cone of rays which theory indicated, should be seen within the crystal when a single external ray corresponding with a ray refracted along an optical axis, was 1°55′ in arragonite. The external ray was divided into two, but when the critical incidence was gained, after much care in the adjustment, Professor Lloyd "at last saw the two rays spread into a continuous circle, whose diameter was apparently equal to their former interval.

"This phenomenon was exceedingly striking. It looked like a small ring of gold viewed upon a dark ground; and the sudden and almost magical change of the appearance from two luminous points to a perfect luminous ring, contributed not a little to enhance the interest.

"The emergent light, in this experiment, being too faint to be reflected from a screen, I repeated the experiment with the sun's light, and received the emergent cylinder upon a small piece of silver paper. I could detect no sensible difference in the magnitude of the circular sections at different distances from the crystal.

"When the adjustment was perfect, the light of the entire annulus was white, and of equal intensity throughout. But when there was a very slight deviation from the exact position, two opposite quadrants of the circle appeared more faint than the other two, and the two pairs were of complementary colours. The light of the circle was polarised, according to the law which I had before observed in the other case of conical refraction. In this instance, however, the law was anticipated from theory by Professor Hamilton."

In addition to these interesting results, Professor Lloyd has published an account of a new case of interference, in which the experimental exhibition of the fact is much more manageable than in the experiment of two slightly inclined mirrors given by Fresnel. Professor Lloyd causes the light reflected at an angle of 90° from the surface of a single piece of plate glass or a metallic reflector, to interfere with the direct light that passes parallel to the reflecting surface and near it. A screen placed on the other side of the mirror receives the direct and the reflected pencils, which, meeting under a small angle, after having traversed paths differing by a small amount, interfere. Professor Lloyd also received the two pencils upon an eye-piece placed at a short distance from the reflector, and saw a very beautiful system of bands, in every respect similar to one half of the system formed by the two mirrors in Fresnel's experiment.

Professor Lloyd has more recently, in 1836 and 1837, communicated to the Royal Irish Academy the results of his researches,[3] *On the propagation of light in uncrystallised media*. His object was to simplify and develope that part of M. Cauchy's theory, which relates to the propagation of light in an ethereal medium of uniform density, and to extend the same theory to the case of the ether enclosed in uncrystallised substances, taking into account the action of the internal molecules. In the first part of his memoir, Professor Lloyd has given good reason for concluding that the theory in its present form is insufficient to explain the phenomena of light in bodies, and that it becomes necessary to take into account the action of the material molecules. In doing this he limits himself to the comparatively simple case, in which the molecules of the ether and the body are uniformly diffused. In the expression for the velocity of propagation, each term consists of two parts, one of which is due to the action of the ether, and the other to that of the body. "It is not improbable," says Professor Lloyd, "that there may be bodies for which the first or principal term is nearly nothing, the two parts of which it is composed being of opposite signs, and nearly equal. In this case the principal part of the expression for the velocity will be that derived from the second term; and, if that term be taken as an approximate value, it will follow, that the refractive index of the substance must be in the subduplicate ratio of the length of the wave nearly. Now, it is remarkable that this law of dispersion, so unlike any

---

[1] The *wave surface* is a geometrical surface employed to determine the direction and the velocity of reflected and refracted rays. It is spherical in a singly refracting medium; a double surface or one of two sheets in a doubly refracting medium; and a surface of three sheets, on the supposition that there is a triple refraction. It has always a centre round which it is symmetrical; and the radii drawn from this centre in different directions represent the velocities of rays to which they are parallel.—*Maccullagh's Irish Trans.* vol. xvii.

[2] *Irish Trans.* vol. xvii p. 136.

History.

thing observed in transparent media, agrees pretty closely with the results obtained by Sir David Brewster in some of the metals. In all these bodies the refractive index (inferred from the angle of maximum polarization) *increases* with the length of the wave. Its value for the red, mean and blue rays, in silver, are 3·866, 3·271, 2·824, the ratios of the second and third to the first, being ·85 and ·73. According to the law above given, these ratios should be ·88 and ·79.

We are indebted also to Professor Lloyd for an admirable history *Of the progress and present state of physical optics*, published in the *Fourth Report* of the meeting of the British Association, held in Edinburgh ; a history not less characterised by its candour and truth, and absence of all national partiality, than by the profound and accurate knowledge of the subject which it everywhere displays. The only cultivator of physical optics to whom Professor Lloyd has done injustice is himself ; and we are glad of the opportunity which we here enjoy, of giving a brief and imperfect account of his original and valuable researches.

Professor Maccullagh.

It is with no less pleasure that we proceed to give an account of the optical discoveries of another Irish philosopher, who, at an early period of life, has placed himself in a distinguished position both as a mathematician and a natural philosopher. We have already seen that M. Ampère gave a direct demonstration of Fresnel's construction for finding the surface of the wave. His solution, however, was extremely difficult and complicated. Mr. James Maccullagh was led in 1829 to believe, from the simplicity and elegance of the results, that there must be some simpler method of arriving at them, and, upon considering the subject with attention, he was led to a concise demonstration of the same theorem, and of some of the other leading points of Fresnel's theory. He has demonstrated a geometrical construction for finding the magnitude and direction of the elastic force arising from a displacement in any direction, and by his construction, with the aid of a few lemmas, he is immediately led to all the conclusions established by M. Fresnel. The magnitude and direction of this force are represented by means of an ellipsoid, having for its semiaxes the three principal indices of the medium, these axes coinciding in direction with, and being inversely proportional to, the axes of Fresnel's generating ellipsoid.

The properties of the wave surface and its use in determining the directions and velocities of reflected and refracted rays, seem to have been discovered independently by Sir W. Hamilton, M. Cauchy, and Mr. Maccullagh, and in a paper entitled, *Geometrical propositions applied to the wave theory of light*, he has applied the properties of that surface to the geometrical development of the theory of double refraction.

Hitherto the remarkable laws of the double refraction of quartz, developed by the successive labours of Arago, Biot, Fresnel, and Airy, were merely a set of independent facts unconnected by any theory ; but Mr. Maccullagh in a paper *On the laws of the double refraction of quartz*, sent to the Royal Irish Academy, in February 1836, has shewn how they may be explained hypothetically, by introducing differential coefficients of the third order into the equations of vibratory motion.

The theory of the action of the metals upon light having been long among the desiderata of physical optics, Mr. Maccullagh thought that it would be important to represent the phenomena of elliptic polarisation, discovered by Sir David Brewster, by means of empirical formulæ, in a manner analogous to that employed by Fresnel in the case of total reflexion. Mr. Maccullagh has applied his formulæ to steel, and in computing from it the intensity of light reflected when common light is used, he obtained the remarkable result, that the intensity decreases very slowly up to a large angle of incidence (less that 75°), and then increases up to 90°, where there is total reflexion. This result entirely accords with the remarkable fact discovered by Mr. Potter,[2] that the intensity decreases with the angle of incidence as far as 70°. Mr. Maccullagh conceives that experiments alone can decide whether the subsequent increase indicates a real phenomenon, or arises from an error in the empirical formulæ.

Mr. Maccullagh deduces also from his formulæ the phenomenon observed by Mr. Airy in the diamond ; and he has applied it successfully to the phenomena discovered by M. Arago, respecting the rings formed between a transparent and a metallic surface. In this experiment Mr. Maccullagh and Prof. Lloyd have both discovered a curious appearance unnoticed by any other author. Through the last twenty or thirty degrees of incidence, the first dark ring surrounding the central spot, which is comparatively bright, remains constantly of the same magnitude, though the other rings dilate greatly by an increase of incidence.

Hitherto the undulatory theory had been unable to give any explanation of the variation of the polarising angle, when the light was reflected in different azimuths from calcareous spar, and other doubly refracting surfaces. Mr. Maccullagh, however, was induced to exercise his mathematical skill on this interesting subject ; and so early as 1834, he communicated to Professor Lloyd an expression for the angle of polarisation at the surface of crystallised media, when the plane of reflexion coincides with the principal section of Fresnel's ellipsoid ; and he found that the law, which he extended by analogy to all cases, represented with much exactness the observations of Sir David Brewster.[3] In a subsequent paper, *on the laws of reflexion from crystallised surfaces*,[4] he has explained the principles upon which his formula is founded. He was obliged to adopt the view of Cauchy, that the vibrations of polarised light are parallel to its plane of polarisation, and being embarrassed by his third ray, he altered Cauchy's six equations of pressure, so as to make them afford only two rays, and give a law of refraction exactly the same as Fresnel's.

It appears, from a subsequent paper of Mr. Maccullagh's,[5] that M. Seebeck[6] had solved the same problem long before, namely, in the case where the plane of incidence coincides with the principal section of the crystal, and had confirmed its accuracy by experiment. M. Seebeck had also pointed out a defect in Mr. Maccullagh's formulæ, No. 2 and 3, which induced the latter to resume the subject ; and in a new paper read to the Irish Academy on the 9th January 1837, a solution of the following problem is given for the first time :—" Supposing a ray of light, polarised in a given plane, to fall on a doubly refracting crystal, it is required to find the plane of polarisation of the reflected ray, and the proportion between the amplitudes of vibration in the incident, the reflected, and the two refracted rays." The hypotheses employed by our author are these, viz.

1. The density of the ether is the same in all media.
2. The vibrations are parallel to the plane of polarisation.
3. The *vis viva* is preserved.
4. The vibrations are preserved ; that is, the resultant of the incident and reflected vibrations are the same as the resultant of the refracted vibrations. " This theory," says the author, " represents very accurately the experiments of Sir David Brewster and M. Seebeck, on the light reflected in air from a surface of Iceland spar."

We owe also to Mr. Maccullagh some interesting views

History. respecting the nature of the light transmitted by the diamond and by gold leaf. He conceives that there is a change of phase produced by refraction, as well as by reflexion, from these bodies, the change being different according as the light is polarised in the plane of incidence, or perpendicular to it. If the incident ray, therefore, is polarised in any intermediate plane, the refracted ray should be elliptically polarised, which was found to be the case in gold leaf. He conceived that the same remark explains the appearance of double refraction in specimens of the diamond which give only a single image, and that other precious stones are likely to have similar properties. Our author has obtained a general formula for the difference of phase between the two component portions of the refracted light, one polarised in the plane of incidence, and the other perpendicular to it. He finds from this formula, that the difference of phase, which is nothing at a perpendicular incidence, increases until it becomes equal to the characteristic, at an incidence of 90°; and when the light emerges into air, the difference of phase is doubled. In submitting this formula to the test of experiment, which Mr. Maccullagh has not yet done, it will be requisite to ascertain that the diamond is not composed of strata of different refractive powers.[1]

M. Lamé. M. Lamé, an eminent professor in the Polytechnic School, has recently endeavoured to determine the laws according to which the molecules of ether and of bodies act upon each other. He arrives at the conclusion that "the action of ponderable matter upon the ether varies in the inverse ratio of the square of the distance, and that the elasticity of the ether itself is proportional to its density." He concludes that the retardation of the vibratory motion, in penetrating into a dense body, will be greater the less the length of an undulation; so that the refraction will be greater for the shorter undulations, a result which he regards as the true explanation of dispersion.

"M. Lamé," says Professor Lloyd, "has endeavoured to connect the phenomena of double refraction with an assumed constitution of the ethereal fluid. He takes the case in which the ether is supposed to be distributed round the molecules of the body in confocal ellipsoidal shells; and he concludes that a vibratory movement, propagated from a vacuum into a body so constituted, will be separated, at its entrance, into two component movements, which will advance with different velocities.

"The two component vibrations, he finds, will be at right angles, and parallel to the lines of greatest and least curvature of the elementary ellipsoids. Thus, the bifurcation of a ray of light on entering a crystallised medium, and the opposite polarisation of the two pencils, are found to be consistent with a molecular constitution such as that described.

"These results are of the highest interest, and will, no doubt, receive an early examination from those engaged in the same department of analysis. Their author seems to be persuaded that his methods will lead him to the mathematical laws of other phenomena, which he conceives to depend, in like manner, on the motions of the ethereal fluid."[2]

In a memoir more recently communicated to the Academy of Sciences, M. Lamé has sought to determine the mode of vibration of the ethereal particles which surround the material molecules in concentric spherical shells of decreasing density. He considers transparent homogeneous bodies as consisting of a multitude of such molecules, distributed uniformly in space, and at distances incomparably greater than their diameter; and he conceives that the waves propagated from the molecules adjoining to the surface of emergence, will produce by interference phenomena resembling the fixed lines in the spectrum.[3] This opinion, however, is in our opinion, incompatible with the actual phenomena of fixed lines.

Introduction. The narrowness of our limits will not permit us to record in this historical sketch many other discoveries which have been recently given to the world, though many of them will be detailed under the heads to which they respectively belong. These discoveries have been made principally by Mr. H. F. Talbot, Mr. Potter, Mr. Dove, and other philosophers.

Having thus given a condensed sketch of the history of optical discovery, from the earliest to the present times, we shall now proceed to the proper subject of this article. As the nature of this work requires that the subject be treated in a very popular manner, we shall pass briefly over those branches of Optics which are generally treated mathematically, and which occupy a prominent part in all ordinary treatises, and occupy our limited space with the more interesting departments of Chromatics, Physical Optics, the Double Refraction and Polarisation of Light, the Explanation of Natural Phenomena, the Laws of Vision, and the Construction of Optical Instruments.

INTRODUCTION.

The ancients confounded the phenomena of vision with those of light, by supposing that when we see external objects something passes from the eye to the object. The phenomena of light, however, are totally independent of those of vision, and have a real existence in nature, whether we suppose them to be objects of vision or not.

1. Light is the element by means of which we see external bodies. These bodies may be divided, in reference to light, into two classes, *self-luminous* and *non-luminous*, or dark bodies. The first class include the sun, the stars, flames of all kinds, and bodies which become luminous by friction, heat, and electrical and magnetical action. Such bodies become visible by the light which they themselves emit, and we then obtain a knowledge of their apparent form. The sun, for example, is seen to be round, and the flame of a candle to be of a conical shape. The second class of bodies, however, are never visible but when placed in the light of self-luminous bodies. It includes the moon and all the primary and secondary planets, of which we see only those portions upon which the sun's light directly falls, and all the other objects upon our own globe. When we bring a lighted candle into a room its light falls upon all the objects in the apartment, and they become visible. These bodies reflect or throw back the light of the candle, and they scatter it in all directions, because they are, generally speaking, visible, wherever we place our eye. But objects also become visible by the light thrown off by non-luminous. When the moon has the form of a sharp crescent, we see the obscure part of its circular disc by the light thrown upon it from the earth, which is at that time almost fully illuminated by the sun. In like manner in the room lighted with a candle, objects are seen in corners and places upon which the light of the candle does not fall. These objects, however, are illuminated by the light of the candle thrown back by the white ceiling and walls of the apartment; and hence the reason why the ceilings and apartments should always be white, and why the walls should be white if we wish to obtain the greatest quantity of light from a given flame. Light.

2. The light thrown off from all bodies whether self-luminous or non-luminous, is of the same colour as themselves. A red hot body, or a stick of red sealing wax, will make a sheet of white paper appear red if held near them.

3. But though coloured bodies throw off light of the same colour with themselves, bodies do not appear of the same colour as that of the light which falls upon them. All

[1] See page 27.

[3] *Id. Id.* (note), and *Ann. de Chimie*, tom. lvii.

Introduction.

bodies which are white in white light, appear of the same colour as that of the light which falls upon them; but other bodies, such as red wax, appear red even in white light, a property which they derive from a peculiar structure acting upon the different colours of which white light is composed. Bodies of this kind when illuminated with lights of different colours, always appear brightest in light of the same colour which they exhibit in white light. Thus a stick of yellow wax is more luminous than a stick of red wax, but the yellow wax will be less luminous than the red wax if we illuminate them both with red light.

4. Bodies in their relation to light, are divided into two classes, *opaque* and *transparent.* An *opaque* body is one that stops the light that falls upon it, such as a piece of coal, or a plate of silver; and a *transparent* body is one which transmits the light through it, such as glass, water, and air. The most opaque body, however, may be made transparent by making it sufficiently thin, and the most transparent one may become opaque by making it sufficiently thick.

5. The opacity of bodies, or their power of intercepting light, gives rise to what is called the *shadows* of bodies. As the shadows of bodies are of the same size as the bodies, we thence deduce the fundamental optical fact, *that light moves in straight lines.* The same fact may be proved in a thousand ways, but most simply by placing three small holes in a straight line. In this case the light will pass through them, but if any one of them deviates from the straight line, the light will be stopped. The same thing is finely seen without any experiment, by admitting light into a dark room through an aperture of an inch wide. Its path, marked out by the floating dust which it illuminates, will be seen to be a straight line.

6. Light issues or radiates in every direction and from every point in the surface of luminous and visible bodies. This fact is proved by the circumstance, that we see such bodies wherever we place our eye. However much we may magnify the bright part of the sun's disc through a telescope, or a sheet of white paper through a microscope, we shall never see any points destitute of light.

7. Light consists of separate and independent *parts*, which, when reduced to the smallest magnitude, are called *rays of light.* A beam of light transmitted into a dark room may be actually divided into smaller portions in a variety of ways. The smallest portion that we can allow to pass may be called a ray of light, and possesses the same properties as the larger beam.

8. *Light moves at the rate of* 192,000 *miles in a second.* This extraordinary property of light has been deduced by direct calculation from the immersions and emersions, in eclipses of Jupiter's satellites, which become visible to us nearly a quarter of an hour earlier when the earth is nearest Jupiter, than when it is farthest from that planet. The exact velocity of light obtained in this manner, is 192,500 miles in a second; whereas, Dr. Brinkley and M. Struve have found it to be 191,515 miles in a second, from the phenomena of aberration.[1] This last determination is undoubtedly the most correct. The mean, however, of 192,000 is most easily remembered.

The velocity with which light travels is so inconceivable, that we require to make it intelligible by some illustrations.

It moves from the sun to the earth in $7\frac{1}{2}$ minutes, whereas a cannon ball fired from the earth, would require *seventeen years* to reach the sun.

Light moves through a space equal to the circumference of the earth, or about 25,000 miles in about the 8th part of a second. The swiftest bird would require *three weeks* to perform this journey.

Light would *demonstrably* require *five years* to move from the *nearest* fixed star to the earth, and *probably* many thousand years from the most remote star seen by the telescope. Hence if a remote visible star had been created at the time of the creation of man, it may not yet have become visible to our system.

9. When light falls upon any body, whether rough or smooth, coloured or uncoloured, a part of the incident light enters the body, and is either lost within it, or transmitted through it; and part of it is reflected from its surface, either in the same or in a different direction from that in which it came. The light which enters the body and is lost, the light which is transmitted through the body, and the light which is reflected from it, suffer certain changes in its direction, and in its physical properties. It belongs to the *geometrical* or mathematical part of optics, to assign the laws which regulate the change of direction which light experiences when it is transmitted through, or reflected from bodies, whose density is uniform, and whose surfaces have a geometrical form; and to *physical* optics, to explain the changes in the physical properties which light acquires in passing through bodies, in passing near them, or in being reflected from their surfaces.

The laws or rules which regulate the reflexion of light, constitute that branch of optics which is called *catoptrics*, and the laws which regulate the changes of deviation which light experiences when transmitted through bodies, is called *dioptrics.*

PART I. CATOPTRICS, OR THE REFLEXION OF LIGHT.

Catop-

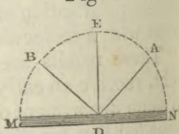
The word *catoptrics*, derived from the Greek words κατα *from*, and ὀπτομαι, *to see*, signifies that department of optics which treats of the reflexion of light from the polished and regularly formed surfaces of bodies, such as *water*, *glass*, and the *metals.*

The name of *speculum* or *mirror*, has commonly been given to bodies that have regularly formed and highly polished surfaces. The word *speculum* is generally applied to polished metals, and *mirrors* to reflectors made of glass and covered with an amalgam of tin and mercury, to increase their power of reflecting light.

There are four kinds of specula used in optics, namely, *plane*, *convex*, *concave*, and *cylindrical*, and when light falls upon any of these specula, which we shall always consider to be formed of polished metal, it is reflected according to the same law.

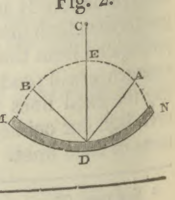
General Law of Reflexion.

Fig. 1.



Let AD be a ray of light which falls upon a *plane speculum* MN, and strikes it at the point D, this ray will be driven back in the direction DB, so inclined to the original ray AD that if we raise from the point D a line DE perpendicular to MN, the angle BDE will be equal to the angle ADE. The ray AD is called the *incident* ray, DB the *reflected* ray, ADE the *angle of incidence*, and BDE the *angle of reflexion.* The two rays AD, DB, and the perpendicular DE, all lie in the same plane AEBD. This plane is sometimes called the *plane of incidence*, and sometimes the *plane of reflexion*,, and it is always at right angles to the reflecting surface MN.

Fig. 2.



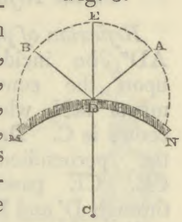
When the reflecting surface is *concave* as MN in fig. 2, and is part of a sphere, whose centre is C, a ray of light AD falling upon any point D, will be reflected in a direction D B, so as to form the same angle BDC with a line CD drawn from the cen-

[1] See ABERRATION, vol. i. p. 31.

tre of the sphere to the point of incidence D, that the incident ray AD does, viz. the angle ADC. In this case the line DC is perpendicular to the reflecting surface at D.

When the speculum is *convex* as in fig. 3, and C the centre of its spherical surface, then if we draw CE, passing through any point D, of the spherical surface MN, any ray of light AD, incident at D, will, after reflection, take a direction DB, having the same inclination BDE to DE, that the incident ray AD has. In this case, also, the prolonged radius of curvature CE, is perpendicular to the surface MN at D.

Fig. 3.



When the surface is cylindrical, the form of the reflecting line, or the line lying in the plane of reflexion, is a circle in one direction, a straight line in another, and an ellipse in all intermediate ones, but in every case the reflected ray will take such a direction that the angle which it forms with a line perpendicular to a plane touching the cylinder at the point where the ray strikes it, will be equal to the angle which the incident ray forms with the same perpendicular. This is true of all curved surfaces whatever.

The results now stated have been established by direct experiment for all inclinations of the incident ray, so that it is a law universally true, that in the reflexion of light *the angle of incidence is equal to the angle of reflexion.* Hence it follows, that when the incident ray is perpendicular to any surface, it is reflected back in the direction in which it came, and when the incident ray is parallel to the reflecting surface, (when plane) or is inclined 90° to it, it will pass on without suffering any change in its direction.

The equality of the angles of incidence and reflexion is finely seen in the game of Billiards, in the reflexion of a hand-ball from a wall, and in the reflexion of sound.

By means of the law of reflection we can easily determine, even without any calculation, the effects produced upon light by specula and mirrors, and the shape, and magnitude, and position of the images of all objects seen by reflexion from them. These effects we shall now proceed to consider in their order.

Definitions. *Parallel rays* are those which are parallel or equidistant, as AD, A′D′, fig. 4.

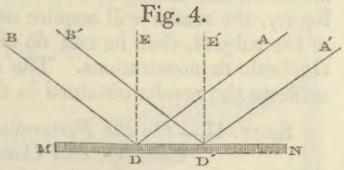
Diverging rays, are those which issue or diverge from a point, and separate from each other, forming an angle as AD, AD′, AD″, fig. 5.

Converging rays, are those which *converge* to a point, or approach to one another, as AD, A′D′, A″D″, fig. 6.

Sect. I.—*On the Reflexion of rays from Plane Mirrors.*

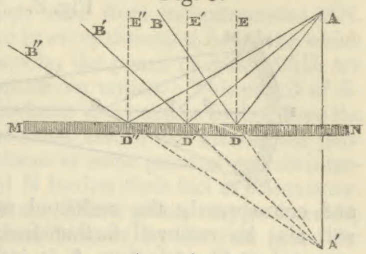
Reflexion of parallel rays. When parallel rays AD, A′D′ fall upon a plane speculum MN at the points D, D′ they will preserve their parallelism after reflexion. Drawing the perpendiculars DE, D′E, make the angles of reflexion EDB, E′D′B′ equal to the angles of incidence ADE, A′D′E′, and it will be found that DB is parallel to D′B′. If the space between AD, A′D′ be supposed to be filled up with other rays parallel to AD, the space between DB and D′B′ will also be filled up with parallel rays. Hence a beam of parallel rays ADD′A′, will be reflected into the parallel beam DB D′B′, the latter being the same as the former but inverted. If the inverted beam suffers another reflexion from another mirror, parallel to MN, it will be restored to a position exactly parallel to AA′DD′, and no longer inverted.

Fig. 4.



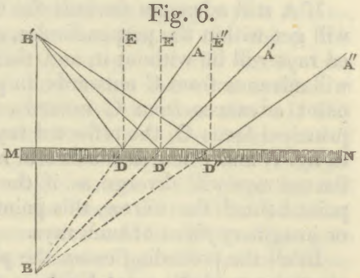
Reflexion of diverging rays. When diverging rays, AD, A′D′, A″D″, fall upon a speculum MN, they will be reflected in directions DB, D′B′, D″B″ found by making the angles BDE, B′D′E, B″D″E″ respectively equal to ADE, A′D′E′, A″D″ E″, and the reflected rays being continued back till they meet, they will be found to meet at a point A′ so that the line AA′ is at right angles to MN, and AN equal to A′N. Hence the rays will have the same divergency after reflexion, as before it, and as if they came from A′, the reflected beam being inverted, as in the preceding case.

Fig. 5.



Reflexion of converging rays. When converging rays AD, A′D′, A″D″, fall upon a speculum MN, they will converge after reflexion to a point B′, so situated, that if BB′ is at right angles to MN, B′M will be equal to BM. The reflected rays DB, D′B, D″B″, will be found by making the angles EDB′ E′D′B′, E″D″B″, respectively, equal to the angles of incidence, ADE, A′D′E,′ A″D″E″.

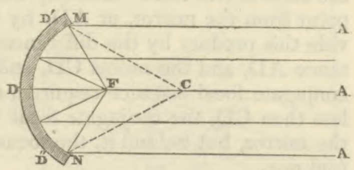
Fig. 6.



On the Reflexion of Rays from Concave Mirrors.

Reflexion of parallel rays. Let MN be a *concave* mirror whose centre of concavity is C, and let parallel rays AD, AD′, A″D″, fall upon the mirror, the central ray AD passing through the centre C. From C draw the lines CD′, CD″. Then since CD′ is perpendicular to the mirror at D′, the ray AD′ will be reflected in the same direction D′F, so that the angle of reflexion CD′F is equal to the angle of incidence AD′F. In like manner, the ray AD will be reflected to E, and the central ray AD will be reflected back to F also; all intermediate rays being likewise reflected to F.

Fig. 7.

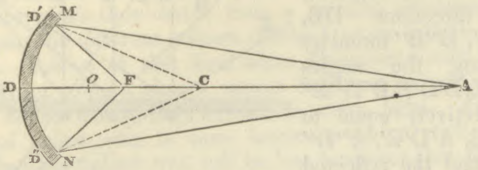


If the curvature of MN is not deep, and if the points D′,D″ are taken near D, it will be found by making the angles of reflexion equal to the angles of incidence, that the rays all meet accurately at F, which is called the *focus* of the mirror for parallel rays, or its *principal* focus. This *focus* is in all mirrors exactly half-way between the centre C, and the surface of the mirror.

The point F derives its name of *focus* from its being the burning point of a mirror, or the point where the parallel rays, issuing from the sun are most condensed, and therefore occasion the most powerful heat.

Reflexion of diverging rays. Let AD, AD′ AD″, be diverging rays issuing from A and falling upon the mirror MN, whose centre is C, and principal focus O. Then if we make the angles of reflexion equal to the angles of incidence, as in the last case, we shall find that the rays will be reflected to a point F, between the centre C of the mirror, and its principal focus O. If the radiant point A is removed from the mirror, and the rays fall on the same points of it, it is manifest that the incident rays will be removed farther from the perpendiculars CD′, CD″,

Fig. 8.



and consequently the reflected rays which meet at F, will also be removed farther from them. Hence F will approach to O, and when A is infinitely distant, and the rays parallel, F will coincide with O. But if A approaches to the mirror, the incident rays will approach to the perpendiculars, and as the reflected rays will do the same, their point of concourse F will approach to C. When A reaches C, the focus F will also reach C, and the reflected ray will coincide with the incident ray.

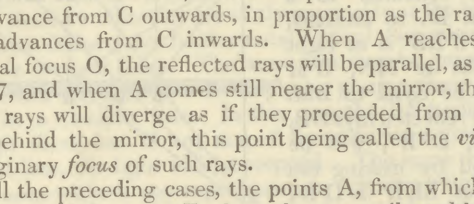
If A still advances towards the mirror, the incident rays will get within the perpendicular, and therefore the reflected rays will be without it, and their point of concourse F will advance from C outwards, in proportion as the radiant point advances from C inwards. When A reaches the principal focus O, the reflected rays will be parallel, as seen in fig. 7, and when A comes still nearer the mirror, the reflected rays will diverge as if they proceeded from some point behind the mirror, this point being called the *virtual* or imaginary *focus* of such rays.

In all the preceding cases, the points A, from which the rays issue, and the point F where they are collected by reflection, are called *conjugate foci,* because if we make A the radiant point, F will be the focus, if we make F the radiant point, A will be the focus.

The conjugate foci of a concave mirror may be easily found by projection. The following rule will give the focus more accurately when the rays AD′, AD″ are not far from the central one AD. Multiply the distance of the radiant point from the mirror, or AD, by the radius CD, and divide this product by the difference between double the distance AD, and the radius CD, and the quotient will be the conjugate focal distance required, or FD. If twice AD is less than CD, the conjugate focal point will not be before the mirror, but behind it, the focus being in that case a virtual one.

Reflexion of converging rays. Let AD, AD′ AD″ be

Fig. 9.



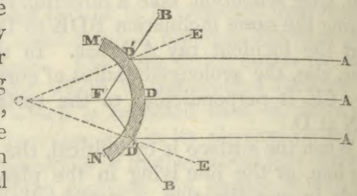
rays converging to a point a behind the mirror MN, whose centre is C. Having drawn CD′ and CD″, make the angles of reflection CD′f, CD″f respectively equal to the angles of incidence AD′C, AD″ C; and D′f, D″f will be the reflected rays having their focus at f, between the mirror and its principal focus F. If the point of convergence a of the rays, or the conjugate focus, approaches to the mirror, the other conjugate focus f will also approach to it, and if it recedes from the mirror, the focus f will also recede, reaching F when a is infinitely distant, in which case AD′, AD″ are parallel, as in Fig. 7. The following is the rule for finding the conjugate foci when one of them is given:

Multiply the distance of the point of convergence from the mirror, or aD by the radius of the mirror or CD, and divide this product by the sum of double the distance aD and the radius CD, and the quotient will be the conjugate focal distance required, namely, fD, the focus f being in front of the mirror.

On the Reflexion of Rays from Convex Mirrors.

Reflexion of parallel rays. Let parallel rays AD, AD′, AD″ be incident upon the convex mirror MN, whose centre is C. Draw the perpendicular CE, CE passing through D′ and D″, and making the angles of reflection EDB, ED″B equal to the angles of incidence, AD′E, AD″E, the reflected rays will be D′B′ D″B, whose virtual focus F is behind the mirror, and so situated that FD is equal to FC.

Fig. 10.



Reflexion of diverging rays. If we suppose the rays AAA to diverge from any point in the line or axis AD, they will recede from CE, CE, consequently the reflected rays D′B, D″B will recede also; that is, will become more divergent, as if they came from a focus between F and D, the virtual focus approaching to D as the radiant point A approaches to D.

Reflexion of converging rays. In like manner, if the rays AAA widen at A, that is, converge to some point behind the mirror MN, they will approach to CE and CE, so that the reflected rays D′B, D′ B will also approach to CE, and consequently diverge less, or have their virtual focus between F and C. When the converging rays coincide with CE, CE, they will be reflected back in the direction in which they came, having C for their virtual focus. When the converging rays pass CE, the reflected rays will also pass to the opposite side, and converge less after reflexion, having their virtual focus beyond C. When they converge to F, the reflected rays will be parallel as in fig. 10, where we may suppose BD′ BD″ the incident, and D′A, D″A the reflected rays. When the rays converge to a point between F and D, the reflected rays will converge to a point in the axis, and as the point of convergency of the incident rays approaches to it on the one side, the point of convergency of the reflected rays will approach to it on the other.

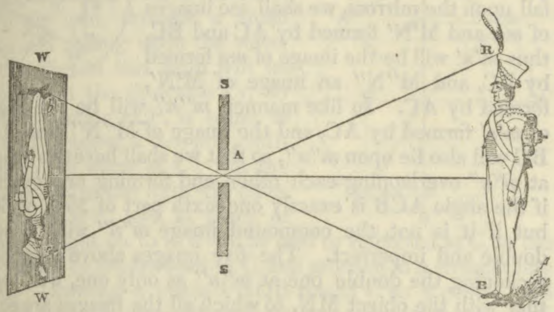
It would have been easy by the simplest elements of geometry, to have demonstrated the preceding truths; but the demonstration would have been rigorous only when the rays fell upon the mirror at points infinitely near D in the axis AD. By finding from projection the foci of rays of all kinds, and falling upon the mirror at all degrees of obliquity, the reader will acquire more substantial knowledge of the subject, than he can do either from geometrical or algebraic demonstrations. The same observation is applicable to the results obtained in the following section.

Sect. II.—*On the Formation of Images by Plane, Concave, and Convex Mirrors.*

Formation of Images by Apertures.—In optics an image is a luminous resemblance or picture of any object whatever, formed either on a white ground, such as a sheet of paper, or suspended in the air.

In order to understand how images are formed, let us suppose that a soldier is standing on the outside of an open window, with a *red coat* and *blue trowsers,* strongly illuminated by the sun. The white wall opposite the window is illuminated by all the light which enters the window, the blue light of the sky, the green foliage, the red coat, and the blue trousers, so that it has no distinct colour, but a mixture of all these. If we close the shutters, so as to allow no light to fall upon the wall but the red light of the coat, and the blue light of the trowsers, it will be illuminated only by a mixture of red and blue light. But if we close all the shutters SS, and leave only a small hole A, about half an

Fig. 11.

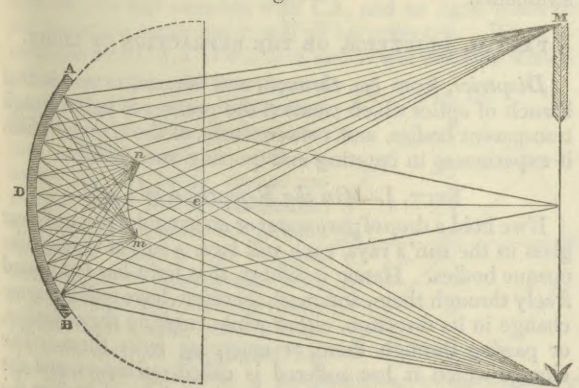


inch in diameter, then it is obvious that the *red* rays at and below R, passing through the hole A, will illuminate the opposite wall at and above *r* with *red* light, and the *blue* rays the opposite point at and below *b* with *blue* light; and that no *red* light can fall upon *b*, and no *blue* light upon *r*. Hence we shall have the *red* body of the soldier rudely shadowed out at and above *r*, and his *blue* legs at and below *b*, this small image being inverted, because the rays from the upper part of his body fall upon the lower part of the wall, and the rays from the lower part of his body upon the upper part of the wall. If we make the hole A smaller and smaller, the inverted image of the soldier will become more and more distinct, the colours will be better separated, and the picture may be made so distinct, that the features of the individual could be recognised. Now this separation of the various lights that at first fell upon the wall is effected solely by diminishing the aperture through which they pass, for if the aperture is exceedingly small, then as no two rays can proceed from the same point, they cannot fall upon or illuminate the same point, and hence each point of the object is represented on the wall by the colour of the light which it throws out.

As the coloured rays from the soldier are thrown off in all directions, an inverted image of that soldier may be formed in any part of space, by excluding all the other rays except those which pass through a small aperture. It is manifest, from a simple inspection of fig. 11, that the size of the inverted image will diminish not only with the distance of the aperture from the soldier, but also with the distance of the ground WW from the aperture.

Formation of Images by Concave Mirrors.—The effect of a concave mirror in forming an image is the same as that of an aperture; but it produces a finer effect, and acts upon a different principle.

Fig. 12.

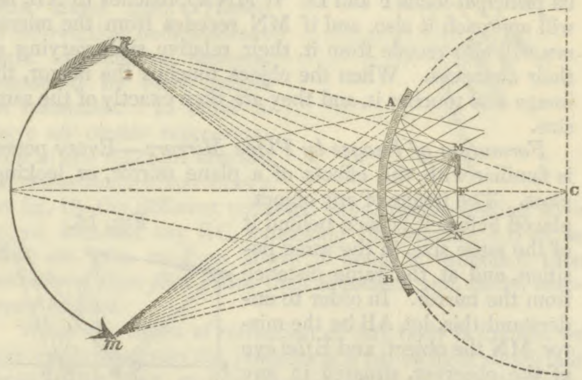


Let AB, fig. 12, be a concave mirror, C its centre, and MN an object placed before it. Of all the rays which flow from every part of this object in every direction, we shall consider only those which issue from its extremities MN. The rays from M radiate in every direction, but those which fall upon the mirror, namely, the pencil or cone MAB, are the only ones which require our notice. This pencil of diverging rays will have its focus at a point *m* farther from the mirror than its principal focus, and in like manner the pencil NAB will have its focus at some point *n*, pencils intermediate between M and N having their foci at points intermediate between *m* and *n*. These points may be found by projection, as already described, or by the rule given for diverging rays.

The image *mn* is obviously an inverted picture of the object MN, and its size is to that of the object as the distance of the image from the mirror is to the distance of the object from it, that is, as *n*A is to NA, as may be found from projection, or from an experimental measurement of the distance, when a mirror is actually used.

From the doctrine of reflected diverging rays it follows, and may be proved by projection, that as the object MN approaches to the mirror, the image *mn* will recede from the mirror, till the object and image meet one another at the centre C, where they will have the same size. If MN still moves towards the mirror within C, the image *mn* will move outwards beyond C, and the image will now be larger than the object. If the object comes to the place *mn*, and is of the same size as *mn*, the image of it will be formed at MN, and will have the same size as MN. If the object goes still nearer the mirror the image will go still farther off than MN, increasing in size. When the object reaches the principal focus half way between C and D, the image will be infinitely distant; and when the object goes still nearer the mirror, as in fig. 13, where it is placed at MN, between the principal focus

Fig. 13.



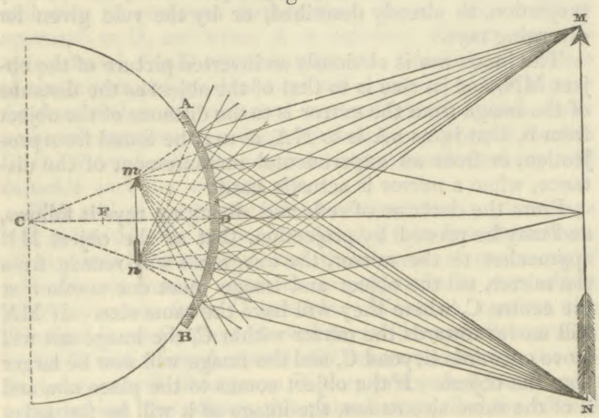
F and the mirror AB, the rays will diverge in front of the mirror, and form an inverted *virtual image*, *mn*, behind the mirror. As the image MN approaches the mirror, the virtual image *mn* also approaches to it.

If we take a concave mirror of some size, and place before it any highly luminous or strongly illuminated object, such as a plaster of Paris cast, we may obtain an interesting experimental proof of the preceding results. When the image is formed in front of the mirror, it will appear suspended in the air, and the effect of this will be greatly heightened if it is received on a cloud of thin blue smoke raised from a chafing dish below the place of the image. By considering that as the object moves from MN to C, fig. 12, the image *mn* advances to C, we obtain an explanation of the celebrated experiment with the dagger mentioned by John Dee, in our history of the science, in which a person with a drawn dagger striking at the mirror is met by another person, viz., his own image, returning the stroke.

If the object MN is the sun, a small image of his disc will be formed at *mn*, in which are collected all the rays of light which fall upon the surface of the mirror. It will therefore have such a degree of heat as to melt even the hardest gems and metals. Such a mirror is called a burning mirror, from its effects.

Formation of Images by Convex Mirrors.—As convex mirrors often form a part of household furniture, we are more familiar with their properties. They always form *erect* images of objects, which appear at a distance behind them.

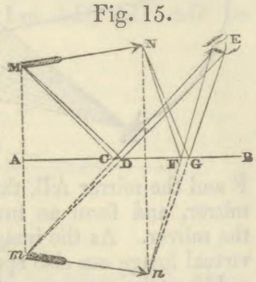
Fig. 14.



If AB is a convex mirror whose centre is C, and principal focus F, and MN an object placed before it, it is obvious, from our description of fig. 10, that the diverging pencils MAB, NBA, will diverge more after reflexion, as if they came from virtual foci *mn* behind the mirror, so that our eye receiving such diverging rays will see an erect image *mn* of the object MN placed behind the mirror, and between its principal focus F and D. If MN approaches to AB, *mn* will approach it also, and if MN recedes from the mirror, *mn* will also recede from it, their relative sizes varying as their distances. When the object touches the mirror, the image also touches it, and they are then exactly of the same size.

Formation of Images by Plane Mirrors.—Every person is familiar with the effects of a plane mirror, or looking-glass. The image of any object placed before it is seen behind it of the same size, in the same position, and at the same distance from the mirror. In order to understand this, let AB be the mirror, MN the object, and E the eye of the observer, situated in any given position. Rays from M and N fall upon every part of the mirror, but MC, MD are the only ones from M which can reach the eye E, as all the rest are reflected either above or below the eye E. In like manner, the rays NF, NG are the only ones from N which can enter the eye. The extremity M of the object will therefore be seen in the direction E*m*, and the concourse or virtual focus of the reflected rays will, as shewn in fig. 6, be at a point *m*, so situated, that if MA*m* is at right angles to the mirror, A*m* will be equal to AM. For the same reason, the point N will be seen at *n*, as far behind the mirror as N is before it; and it is obvious, from the parallelism of M*m* and N*n*, and the equality of the distance of M, *m*, and N, *n* from AB, that *mn* is equal to MN.

Fig. 15.



If two plane mirrors are inclined to each other, as AC, B, fig. 16, and an object MN placed between them, an eye situated so as to receive the reflected rays, will see a series of images of MN all arranged symmetrically. Behind AC, for example, an image *mn* will be formed, and behind BC another image M′N′. But as the rays which form these images again fall upon the mirrors, we shall see images of *mn* and M′N′ formed by AC and BC, thus *m′n′* will be the image of *mn* formed by BC, and M″N″ an image of M′N′, formed by AC. In like manner, *m″n″* will be the image of *m′n′* formed by AC, and the image of M″N″ formed by BC will also lie upon *m″n″*, so that we shall have two images at *m″n″* overlapping each other, and forming one exactly, if the angle ACB is exactly one-sixth part of 360°, or 60°; but if it is not, the compound image *m″n″* will be seen double and imperfect. The five images above described, reckoning the double one at *m″n″* as only one, will, together with the object MN, to which all the images are equal and similar, constitute a perfect equilateral triangle, so that if MN is a coloured and an irregular object, the symmetrical figure composed by it, and all its images, will be highly beautiful and agreeable to the eye. If MN, in place of being perpendicular to the mirror BC, had been inclined to it, no pair of images would have formed a straight line, as in the figure, and the combination would have been more beautiful. This is the principle of the *Kaleidoscope*, in as far as the multiplication and arrangement of the images is concerned; but this instrument has already been so admirably described by an eminent writer, in our article KALEIDOSCOPE, that we must refer the reader to it for farther information.

Fig. 16.

Formation of Images by Cylindrical Mirrors.—It is not easy, in a diagram, to represent the progress of rays in the formation of an image by a cylindrical mirror. As a cylinder is in one direction a plane mirror, in another a convex mirror, and in all others an elliptical one, the eccentricity of the ellipse passing through all degrees, from a circle to a straight line, different parts of a regular figure presented to such a mirror will appear of different sizes, and at different distances behind it. Part of the figure will have the same form and position as in a plane mirror, part as in a convex mirror, and the other parts of the image will have intermediate sizes and positions. Hence the image will be completely distorted. If the mirror is placed horizontally, the human face will appear of the right size from ear to ear, but contracted, as in a convex speculum, from brow to chin. Hence, if a distorted picture is properly drawn, and properly presented to the mirror, that is, if the cylinder is placed vertically before the picture, the image of the distorted picture will be rectified; the length between the ears will be contracted into the same proportional size as the shortness between the brow and the chin, and their shortness will remain unaffected. Such a distorted picture will be afterwards represented in the part of this article on Optical Instruments.

PART II. DIOPTRICS, OR THE REFRACTION OF LIGHT.

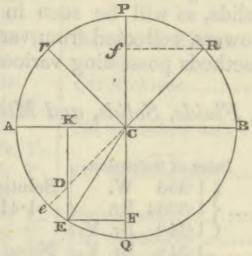
Dioptrics, from δια, *through*, and ὀπτομαι, *to see*, is that branch of optics which treats of the passage of light *through* transparent bodies, and, consequently, of the changes which it experiences in entering and quitting such bodies.

SECT. I.—*On the Refraction of Light.*

If we hold a drop of pure water or an irregular piece of clear glass in the sun's rays, each will have a sort of shadow like opaque bodies. Hence it follows, that light has not passed freely through them, and must, therefore, have suffered some change in its direction, either while entering these bodies, or passing through them, or emerging from them. The change which it has suffered is called *refraction*, and the nature of this change will be discovered by observing the effects produced upon light by transparent bodies, whose surface is flat and regular.

For this purpose let AB, fig. 17, be the surface of *water* in a vessel, and RC a ray or pencil of light proceeding from a candle or from the sun, through a small hole, and falling upon the water at C. Part of this light will be *reflected* in the direction C*r*, so that the angle *r*CP, is equal to RCP, PQ being a line perpendicular to the water at C; but the greater part of the light will enter the water at C, and in place of going straight on to *e*, it will be *bent* or refracted at C, or the ray R*e* will be *broken back* at C, and proceed in a straight line to E. Drawing a circle PAQB round C as a centre, and from the point E, where the refracted ray cuts it, drawing EK parallel to PQ, it was found by Snellius that CD was to CE or C*e* as 3 to 4, and we have shewn in the history of optics, that if R*f* and EF are drawn perpendicular to PQ, CD is to C*e* as EF is to R*f*. But R*f* is the sine of the *angle of incidence* RCP, and EF is the sine of the angle ECQ, which is called the *angle of refraction*. Now, Snellius discovered by numerous experiments, that whatever was the magnitude of the angle of incidence RCP, the magnitude of the angle of refraction was such that CD was to C*e* as 3 to 4, or in a constant ratio. Hence it follows, that the sines of the angles of incidence and refraction R*f* and EF, are in the case of water in the constant ratio of 4 to 3.

Fig. 17.

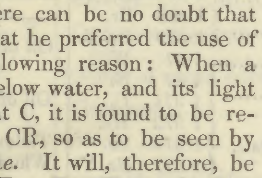


Snellius in his manuscripts did not mention the *constant ratio of the sines*, but merely the *constant ratio of CD and Ce*, which is the same. The ratio of the sines was first mentioned by Descartes, but there can be no doubt that Snellius knew it perfectly, and that he preferred the use of the ratio of CD to C*e*, for the following reason: When a luminous body is placed at E below water, and its light passes through a small aperture at C, it is found to be refracted or bent into the direction CR, so as to be seen by an eye at R, in the direction R*e*. It will, therefore, be seen, as it were, elevated from E to D. Hence Snellius preferred giving the law of this elevation, to any other law not connected with the phenomena.

As the incident ray RC approaches to the perpendicular PQ, the refracted ray CE approaches also to the perpendicular, and CD becomes less and less, and when RC coincides with PC, or when the ray is incident perpendicularly, the refracted ray CE will coincide with CQ, or the incident ray will suffer no refraction at C. When the angle of incidence RCP increases, and RC approaches to the surface of the water CB, the angle of refraction ECQ will also increase, the line CD will increase, and the refracted ray approach also to the surface CA, and when RC coincides with BC, C*e* will coincide with CA, and no light whatever will enter the water but it will all be reflected. When C*e* coincides with CA, CD will be 3, and D will coincide with K.

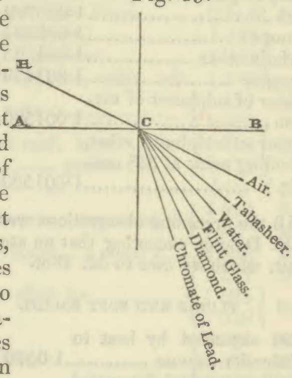
Such are the phenomena and law of refraction when light passes from a rare medium such as *air*, into a dense medium such as *water*, the ray being always *refracted from* the perpendicular, according to the fixed law already described. Let us now suppose, that the ray of light passes from a dense medium, such as water placed above AB, into a rare medium, such as air placed below AB, and let PQ be a perpendicular to the surface of the water at C. It is found by experiment that the ray neither goes straight on to *e*, nor is refracted towards the perpendicular as before, but is refracted from the perpendicular into the direction CE, so that if the line KED is drawn through E, parallel to PQ, and cutting the original direction of the ray R*e* prolonged, in the point D, CD will be to CE or C*e* as 4 to 3, and in a constant ratio, or R*f* the sine of the angle of incidence will be to EF the sine of the angle of refraction in the constant ratio of 4 to 3. When the ray RC coincides with PC, so that the angle of incidence is nothing, the angle of refraction will also be nothing, and the refracted ray CE will coincide with CQ, the incident ray having gone straight on without experiencing any refraction; but when the angle of incidence increases, and RC approaches towards BC, the refracted ray CE will approach to CA, which it will reach long before R reaches B. When CE reaches CA, the ray RC will no longer emerge from the water into the air, but will suffer what is called *total reflexion* at C, and at every angle of incidence beyond that at which this total reflexion commences, the light will continue to be totally reflected till RC coincides with RB.

Fig. 18.



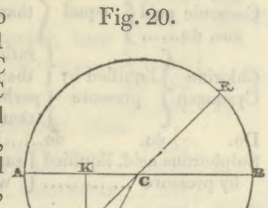
If we repeat all the above experiments with *plate* or *crown glass*, in place of *water*, we shall find the very same phenomena reproduced, with this difference only, that the constant ratio of CD to C*e*, or of the sines R*f* to EF, in place of being as 3 to 4 in one case, (see fig. 17,) and 4 to 3 in the other (see fig. 18,) will be as 2 to 3, and as 3 to 2, or in the case of water the ratio will be as 1 to 1·333, and in glass as 1 to 1·500. The number 1·333 is called the *index of refraction* for *water*, and 1·500 the *index of refraction* for *glass*. In like manner it is found that the index of refraction for *tabasheer* is 1·111, being less than that for water; for flint glass 1·600, for diamond 2·500, and for chromate of lead about 3·00. Hence it follows, that bodies refract light in different degrees, measured by their indices of refraction. In order to have an ocular representation of the different degrees of refraction, we have drawn in fig. 19, the different refracted rays, corresponding to a given incident ray RC, supposing the surface AB to be first *air*, (the medium above it being a vacuum), then *tabasheer*, then *flint glass*, then *diamond*, and, lastly, *chromate of lead*.

Fig. 19.



When the index of refraction of any body is known, we can easily ascertain the progress of a ray of light which falls upon such a body, and its direction after quitting the body. The following example of this we shall give for plate glass. Let AB be the surface of a piece of plate glass whose index or ratio of refraction is as 2 to 3, or as 1 to 1·50, and let a ray of light RC fall upon it at C. Prolong RC to *e*, and upon a scale of equal parts take in the compasses CD, equal to 10 of these parts, and C*e* equal to 15, or CD equal to 2, and C*e* to 3 parts. Upon C as a centre with the radius C*e* describe the semicircle A*e*B, and through D draw KDE, perpendicular to AB, and meeting the semicircle in E, join CE, and CE will be the refracted ray. When the ray passes from a denser to a rarer medium, as in fig. 18, C*e* is made equal to 10, and CD to 15, and DK being drawn perpendicular to AB, and a line

Fig. 20.



drawn from C to the point E, where DK cuts the circle, CE will be the refracted ray. This method, which is obviously much more simple and elegant than when we use the sines of the angles, is, so far as we know, new, and we shall use it in future for determining the place of the refracted ray. It is obvious, that when D and K coincide with A, fig. 18, DK becomes a tangent to the circle at A, and the light suffers total reflexion.

If the preceding experiments are repeated with various solids and fluids, it will be found, that the same law of refraction takes place with all of them, the index of refraction varying more or less in each, the refractive power being least in the gases, and less in fluids, generally speaking, than in solids, as will be seen in the following table of refractive powers, collected from various authors, and determined by methods possessing various degrees of accuracy.

Table of the Refractive Powers of Gases, Fluids, Solids, and Metallic Bodies.

	Index of Refraction.	
A vacuum	1·0000	
GASES.[1]		
Hydrogen	1·000138	
Oxygen	1·000272	
Atmospheric air	1·000294	
Azote	1·000300	
Nitrous gas	1·000303	
Carbonic oxide	1·000340	
Ammonia	1·000385	
Carburetted hydrogen	1·000443	
Carbonic acid	1·000449	
Muriatic acid	1·000449	
Hydrocyanic acid	1·000451	
Nitrous oxide	1 000503	
Sulphuretted hydrogen	1·000644	
Sulphurous acid	1·000665	
Olefiant gas	1 000678	
Chlorine	1·000779	
Protophosphuretted hydrogen	1·000789	
Cyanogen	1 000834	
Muriatic ether	1·001095	
Phosgene	1·001159	
Vapour of sulphuret of carbon	1·001500	
Vapour of sulphuric ether, (boiling point at 35° centig.)	1·001530	

All the preceding observations were made by M. Dulong, excepting that on atmospheric air, which we owe to M. Biot.

In the preceding Table, the letter *N* affixed to any index of refraction, indicates that the observation was made by Newton; *H*, Hauksbee; *E*, Euler; *M*, Malus; *C*, Cavallo's table; *Ru*, Rudberg; *Bi*, Biot; *Po*, Potter; *Ze*, Zeiher; *Bosc*, Boscovich; *Fr*, Fraunhofer; *He*, Sir John Herschel; *F*, Mr. Faraday; *Hai*, Haidinger; *W*, Wollaston; *Br*, Sir David Brewster; and *Br. Y*, by Dr. Young, who calculated the indices from Sir David Brewster's observations.

[1] Deduced from its polarising angle, which was 65°.

If light is regarded as consisting of material particles, it must move with greater velocity in bodies than in vacuo, in the proportion of the sines to which the refraction of these bodies is proportional. The power of bodies, therefore, to refract and reflect light, must be inversely proportional to their specific gravities; for if a body of small specific gravity has the same index of refraction as a body of great specific gravity, the former must have exercised a greater absolute force upon light than the latter.

On the hypothesis of emission, it has been shewn by Sir Isaac Newton, that the absolute refractive power of bodies is proportional directly to the square of the cosine of their maximum angle of refraction, and inversely to their specific gravity; that is, calling R the absolute refractive power, m the index of refraction, and D the density of the body, we shall have $R=\frac{m^2-1}{D}$, a formula by which the following table of absolute refractive powers has been computed. The numbers marked *Dulong*, were, we believe, computed by Sir John Herschel, from the refractive indices given by Dulong in the preceding table.

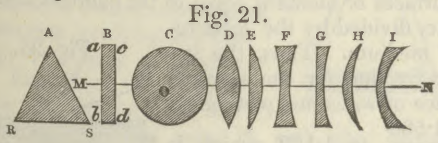
The results given in the preceding tables are susceptible of increased accuracy, not only by taking accurate measures of the indices of refraction of the bodies, in relation to the fixed line E of the spectrum, but also by obtaining more accurate measures of their specific gravities.

SECT. II.—*On the Refraction of Rays by bodies with plane and spherical surfaces.*

Having shewn how to find the refracted ray, when the incident ray is given, and the constant ratio of refraction which belongs to any transparent body, we may trace the progress of rays through bodies of any form whatever, provided we have the lines given which are perpendicular to the surface of the body at the points where the rays fall upon it. In all spherical surfaces this perpendicular is a line drawn through the point of incidence and the centre of the spherical surface; and in all other cases it is a line perpendicular to a line touching the surface at the point of incidence.

The names of *prisms* and *lenses* have been given to those transparent bodies which are most useful in optical experiments, and in the construction of optical instruments. Sections of these different refracting bodies are shewn in the annexed diagram.

Fig. 21.



1. A *prism*, represented in the figure at A, is a solid piece of glass, having three plane surfaces, AR, AS, RS, which are called its refracting faces, the light passing through any two of them.

2. A *plane lens*, B, is a lens, the centre of whose surfaces are infinitely distant. Its sides are therefore parallel like a piece of plane glass.

3. A *spherical lens*, C, is a lens whose surfaces have the same centre, and is consequently a sphere or a part of one.

4. A *double convex lens*, D, has two convex spherical surfaces, whose centres are on opposite sides of the lens. It is said to be *equally convex* when the radii of its two surfaces are equal; and *unequally convex* when the radii are unequal.

5. A *plano-convex lens*, E, is a lens which has one of its surfaces flat or *plane*, and the other *convex*.

6. A *double concave lens*, shewn at F, is a solid bounded by two concave spherical surfaces. It is *equally concave* when its surfaces have the same radius, and *unequally concave* when they have different radii.

7. A *plano-concave lens*, G, has one of its surfaces concave and the other plane.

8. A *meniscus lens*, H, has one of its surfaces *concave* and the other *convex*, the two surfaces meeting if continued. The convexity predominates, and it acts as a convex lens.

9. A *concavo-convex lens*, I, differs from the meniscus only in the circumstance that the two surfaces do not meet if continued. Hence the concavity predominates, and the lens acts as a concave one.

[1] Assuming the specific gravity to be 1·044, the same as oil of cinnamon.

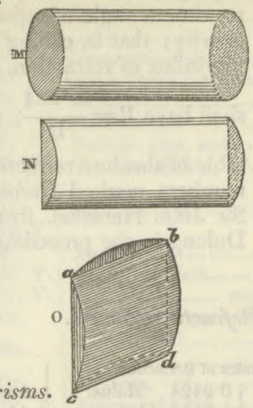
Dioptrics.

10. A *cylindrical lens* is shewn at M; it is merely a cylinder of glass, or any other transparent body.

11. A *plano-cylindrical lens*, shewn at N, has one of its surfaces plane and the other cylindrical.

12. A *transverse cylindrical lens*, shewn at O, resembles two plano-cylindrical lenses, plane transversely, or with their lengths at right angles to each other, and joined together by their plane surfaces at *a b c d*.

Fig. 22.

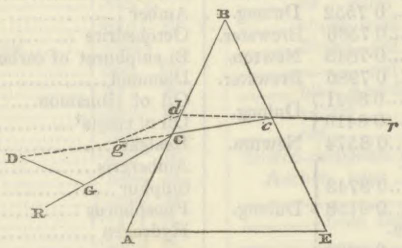


Refraction through Prisms.

As prisms are essential parts of optical instruments, and are of peculiar value in experiments on light, it is necessary to have a correct idea of the phenomena which they exhibit, in refracting rays of light.

Let ABE be a prism of two equal sides BA, BE, and made of glass whose index of refraction is 1·500, or whose ratio of refraction is as 1·500 to 1, or as 3 to 2, and let RC be a ray incident on its first surface at C. It is required to determine the path of this ray after it has suffered refraction at both its surfaces AB, BE. From any scale set off CG equal to 10 divisions, and CR equal to 15, and through G draw GD perpendicular to AC. From the point C, and on the line CD, set off CD equal to CR, and through D and C draw D C*c*,—C*c* will be the refracted ray. From a scale on which C*c* is 10, set off *c*G equal to 15 parts, and drawing *gd* perpendicular to BE, make *cd* equal to *c*C, and draw through *d* and *c* the line *dcr*,—*cr* will be the path of the ray refracted by the second surface BE of the prism. When the radius C*c* will not reach the perpendicular *gd*, the ray C*c* will not be refracted at all, but will suffer total reflexion. When total reflexion commences, the point *d* will fall in the line EB, and the perpendicular *gd* will touch the circle described with the radius *c*C round *c*, at the point *d*. At all greater angles of incidence the ray C*c* will be totally reflected.

Fig. 23.



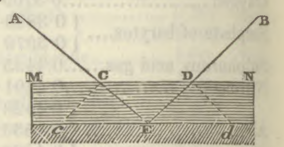
The sine of the angle of incidence at *c*, when the ray C*c* is not able to emerge from the prism, but suffers total reflexion, will be found in the case of plate glass (whose index of refraction is 1·500), to be equal to $\frac{1}{1{\cdot}500}$, or $\frac{2}{3}$, or 0·666; the angle corresponding to which is 41° 48′.

The total reflexion which thus takes place within transparent bodies, is a very remarkable and highly interesting phenomenon. The light is far more brilliant than what is obtained from the brightest silver, which gives more reflected light than any other metal; and it possesses curious physical properties, which will be explained in a subsequent part of the article. The phenomenon of total reflexion may be finely seen by filling a tumbler-glass with water, and placing it above the head so as to see the image of a candle reflected from the lower side of its surface when at rest. The brilliancy of the image surpasses that of every other species of reflexion. Diamonds, precious stones, and the glass ornaments of chandeliers, &c. &c., are often cut so as to send to the eye light that has suffered total reflexion. The brilliant white lustre of dew-drops arises from totally reflected light.

Dioptrics.

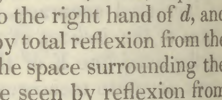
To a person under perfectly still water, the vision of objects either out of the water or on the bottom, must be very singular. The whole visible heavens, in place of being a hemisphere, will appear like a cone, with an angle of 97°. "All objects," says Sir John Herschel, "down to the horizon, will be visible in this space, and those near the horizon much distorted and contracted in dimensions, especially in height. Beyond the limits of this circle will be seen the bottom of the water and all subaqueous objects, reflected, and as vividly depicted, as by direct vision. In addition to these peculiarities, the circular space above mentioned will appear surrounded with a perpetual rainbow of faint but delicate colours." In order to understand this, let MN be the surface of the water, and E an eye at the bottom. Let DE be the direction in which a horizontal ray ND, would be refracted at D, and CE the direction in which MC would be refracted at C. Then it is clear that all objects on the horizon will be seen in the directions ED, EC, and as the same is true in every azimuth, ACEDB will be a section of the cone, which will comprehend within it all objects in the visible horizon. The sun and moon will appear to rise at A and set at B. They will have the appearance of ovals, with their smaller diameters vertical. They will quit the horizon, and descend to it again very slowly, as the angle of refraction varies very slowly from 90° of incidence downwards. If a man fishing near N stands up to his knees in water, his knees will just be seen above the water, in the direction EB, and his body standing within the cone BEA, while his legs will be seen bright, and inverted in the direction of about EN, by the total reflexion of the lower surface MN, of the water. If we draw C*c* and D*d*, making the angles *c*CE, *d*DE, equal to CED, then all objects in the water, to the right hand of *d*, and to the left hand of *c*, will be seen by total reflexion from the inner surface MN of the water, in the space surrounding the cone AEB. An object at *c* will be seen by reflexion from the point C, in the direction EC, and an object at *d* by reflexion from D; but none of the objects between *c* and *d* will be seen by reflexion to the eye at E. Hence we see the reason why the fisherman's legs, like other objects under water, will be seen by total reflexion in a direction near to EN. The circular rainbow, or rather fringe of colours, which separates the objects out of the water from those which are beneath it, and seen by total reflexion, is that band of colour which always bounds light that is totally reflected.

Fig. 24.



It frequently happens, both in optical experiments and in optical instruments, that light is refracted at the surfaces of two media placed in contact, such as water and glass, and in compound lenses of flint and crown glass, either touching one another or united by a cement. In all such cases, it is necessary to determine the refraction which light experiences at their refracting surface. It is found by experiment, and may be proved theoretically, that the index of refraction for the separating surfaces of media is equal to the quotient of the most refractive, divided by the least refractive medium. Thus, the index of refraction for the separating surface of water and plate glass will be $\frac{1{\cdot}500}{1{\cdot}336}$, or 1·122, which is nearly the same as that of tabasheer. In order, therefore, to find the refracted ray in this case, let MN be

Fig. 25.



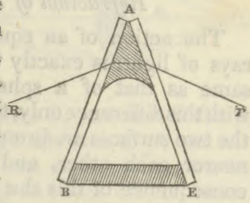
a parallel stratum of water resting upon a piece of parallel glass OP. A ray RC, will be refracted in the direction Cc', and may be found by the method formerly given. In order to find the change produced in the direction of the ray at c', take a point g', in the line c'C, so that if c'C is 1·122, $c'g'$ shall be 1·000, then drawing $g'd'$ perpendicular to the refracting surface, make $c'd'$ equal to c'C; and having drawn through the points d', c' the line $d'c'c'$,—$c'c$ will be the refracted ray. This ray being incident on the second surface of the glass plate at c, will be refracted in a direction cr, which may be found by the method formerly described. It will be found both by projection and by experiment, namely, by looking through the compound plate MNOP, and observing any distant object, that the finally refracted ray cr is parallel to the incident ray RC.

If the angle RCA, fig. 23, the complement of the angle of incidence, is increased, the point c, where the refracted ray emerges from the side BE of the prism, approaches to E, and the angle rcE diminishes, till at a particular inclination of the incident ray, the angle RCA will become equal to the angle rcE. When this happens, the refracted ray Cc, will be equally inclined to the refracting faces of the prism BA, BE, and will be parallel to the base AB. This will be obvious by considering Cc as an internal ray incident on both sides of the prism, and at equal angles to each, in which case it will suffer equal degrees of refraction, and therefore be equally inclined to the refracting faces.

If the eye is placed at r to receive the refracted ray cr, it will see the luminous body, such as a candle, from which the ray RC proceeds, in the direction rc, and the angle which this ray rc forms with RC, will be the deviation of the ray produced by the refraction of the prism. Let us now suppose the candle to be fixed, and the prism turned round, so that the angle RCA may be increased, it will be found experimentally, and may be easily proved by projection, that the deviation of the ray rc is *least* when the angle RCA is equal to rcE, or when Cc is parallel to AE, and increases when Cc deviates on either side from this mean position. Now this position may be easily ascertained by placing the eye behind the face BE, and turning the prism till the refracted image of the candle, or other object, becomes stationary. When this takes place, Cc is parallel to AE or CcA is an equilateral triangle; and it may easily be shewn, by similarity of triangles, or by projection, that *the angle of refraction at the first surface is equal to half the angle of the prism, or* $\frac{1}{2}$ ABE. Hence we obtain the following simple rule for finding the index of refraction, after having measured, with a goniometer or otherwise, the angle of incidence, or the complement of the angle RCA. Divide the sine of the angle of incidence by the sine of half the angle of the prism, and the quotient will be the index of refraction.

For the purpose of measuring indices of refraction, we do not require regular prisms of considerable size. Two small faces well ground and tolerably polished, are sufficient for this purpose. They need never be larger than the pupil of the eye, and will answer well enough if they are of the size of a pin's head. If we wish to measure the index of refraction of fluids, we have only to place a drop of the fluid at the angular point A, of two pieces of parallel glass fixed at any angle by a piece of wood or wax BE. Enough of the fluid for the purpose will be retained, by capillary attraction at the point A, and after measuring the angle BAE of the prism, and the angle of incidence at which the image of the candle becomes stationary, the index of refraction will be found as before.

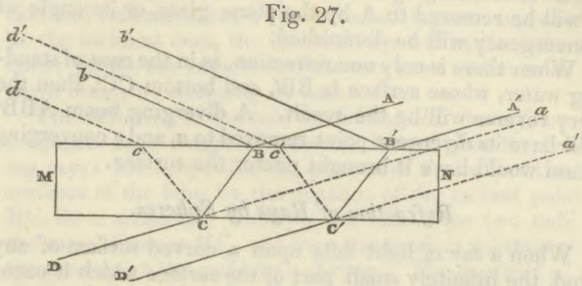
Fig. 26.



Refraction through Plane Glasses.

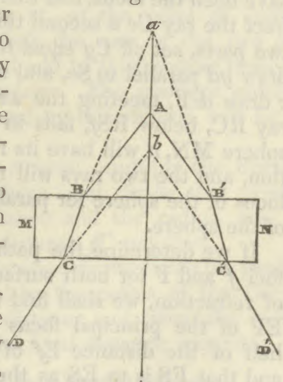
Every person is acquainted with the fact that light which passes through plane glasses, or glasses which have their two surfaces flat and parallel, like MN, in the annexed figure, does not suffer any very perceptible change, either in its general direction, or in the parallelism, convergency, or divergency of its rays. If AB, A′B′, for example, be two parallel rays incident on the plate of glass MN, they will suffer equal refractions at B, B′, because they are incident at the same angles, and the refracted rays BC, B′C′, will therefore be parallel. These parallel rays again falling upon the second surface at C, C′ will suffer equal refractions there, and will emerge parallel in the lines CD, C′D′. Hence we conclude that parallel rays after transmission, at any obliquity, through a plane glass, will emerge parallel. But as the rays DC, D′C′, will, to an eye at D and D′, be seen in the directions DCa, D′C′a', their absolute directions in space are altered, and the difference between the real and the visible direction will increase with the obliquity of the rays AB, A′B′, and with the thickness of the plate of glass. If we suppose MN to be part of a looking-glass, silvered on its lower side CC′, then the refracted rays BC, B′C′, will, after reflexion at C, C′, in the directions Cc, C′c', be refracted at c, c', into the parallel directions cd, $c'd'$. But the rays AB, A′B′, will be reflected, though in a much fainter degree, in the directions Ab, A′b', so that an eye placed so as to receive these rays, will see the bright image reflected from the silvered surface, in the direction dc, and the faint image reflected from the first surface, in the direction bB, at a distance from each other depending on the obliquity of the reflexion, and on the thickness of the plate. A candle, for example, will be seen double at a short distance from the mirror; but a larger object, in order to be seen double, must be viewed at a greater distance. At great obliquities, and when the objects are very luminous, such as gas-burners, &c., other images will be seen by reflexions at c, c', and subsequent reflexions from the other side of the plate. If the two faces of the plate are not exactly parallel, the bright and faint images above described, will change their distance, sometimes overlapping each other, and sometimes separating, according to the part of the plate on which they fall, though the angle of incidence may remain the same.[1]

Fig. 27.



When *diverging* and *converging* rays pass through a plane glass, their degree of divergency and convergency is altered by it,

Fig. 28.



[1] We had once a looking-glass of this kind sent to us as a curiosity by a gentleman, who valued it on account of its remarkable properties. It differed from all the rest in his possession, only in its being the worst.

Dioptrics.

and also the position of the points of divergency and convergency. Let ABB′ be a pencil of rays diverging from A, and incident upon the plane glass MN. The emergent rays CD, C′D′, will, after their second refraction at C, C′, proceed as if they had come from the point *b*, and their angle of divergency will now be *b*BB′. Hence a plane glass brings the divergent point of diverging rays nearer to it, and increases the angle of divergency. For the same reason, if D*b*D′ is a converging beam of light, its point of convergency *b*, will be removed to A by the plane glass, or its angle of convergency will be diminished.

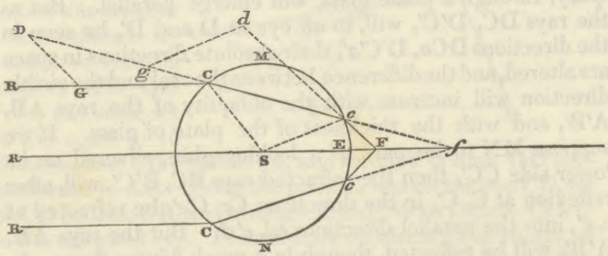
When there is only one refraction, as in the case of standing water, whose surface is BB′, and bottom CC′, then the very reverse will be the result. A diverging beam ABB′ will have its divergent point removed to *a*, and a converging beam would have it brought nearer the surface.

Refraction of Rays by Spheres.

When a ray of light falls upon a curved surface of any kind, the infinitely small part of the surface which it occupies may be considered as coinciding with the tangent to the surface, or with a plane surface touching the curve at the point of incidence. When the surface is spherical, this tangent plane is perpendicular to the radius, or the line drawn from the centre of the sphere to the point of incidence. Hence it is always given when the centre is given.

Let MN be the section of a sphere of glass, whose index of refraction is 1·500, as before, RS*f* a ray passing through

Fig. 29.



its centre S, and therefore unrefracted, because it is incident perpendicularly on both surfaces, and RC, RC, other rays parallel to, and equidistant from, RS*f*, it is required to find the path of one of these RC, through the sphere. Join SC, which will be perpendicular to the surface at C. From a scale on which RC is three parts, set off RC equal to 1, and draw CD parallel to CS, (which is the same as drawing it perpendicular to the elementary surface, or tangent to the sphere at C). Make CD equal to CR, and through D and C draw the line DC*f*, meeting the posterior surface of the sphere at *c*, and the axis of the sphere at *f*. The point *f* would have been the focus, had there been no second surface to refract the ray C*c* a second time. On a scale in which C*c* is two parts, set off C*g* equal to 1 part, and having joined S*c*, draw *gd* parallel to S*c*, and make *cd* equal to *c*C. Through *c* draw *dc*F, meeting the axis of the sphere in F. As the ray RC, below RS*f*, falls in the very same manner on the sphere MN, it will have its refracted ray in a similar direction, and the two rays will meet at F, which is called the focus of the sphere for parallel rays, or the principal focus of the sphere.

If we determine the path of the ray RC, and find the foci *f* and F for both surfaces; by using different indices of refraction, we shall find that in every case the distance EF of the principal focus of the sphere is exactly one-half of the distance E*f* of the focus for the first surface, and that FS is to ES as the sine of incidence or the index of refraction is to the difference between twice the sine of incidence and twice the sine of refraction; that is, in glass as 1·500 is to 3·000—2·000, or as 1·500 to 1·000.

Dioptrics.

Hence we have for different refractive bodies the following results :—

	Index of refraction.	
Tabasheer,......FS is to ES as	1·111	is to 0·222
Watcr,..........FS is to ES as	1·336	is to 0·672
Glass,...........FS is to ES as	1·500	is to 1·000
Zircon,..........FS is to ES as	2·000	is to 2·000

Hence it appears that in the case of zircon, and all other bodies whose index of refraction is 2·00, the focus F falls exactly on the posterior surface of the sphere at E, and it therefore follows that in diamond, phosphorus, &c., and all bodies whose refractive power exceeds 2·000, the principal focus falls *within the sphere*, the focus advancing from E towards S, as the index of refraction increases, and reaching the centre of the sphere S, when the index of refraction becomes infinite.

It may be interesting to trace the distances E of the principal focus F from the sphere, in bodies of various refractive powers, supposing the radius of sphere to be one inch, and placed in vacuo.

	Distances E F.	Feet.	Inches.
Hydrogen,..........	3623 inches............	301	11
Oxygen,.............	1838 —	153	2
Atmospheric air,...	1701 —	141	9
Phosgen,.............	432 —	36	0
Tabasheer,..........	4	0	4
Watcr,................	0·98 —	0	1 nearly.
Glass,................	0·50 —	0	½ an inch.
Zircon,...............	0·00 —	0	0
Diamond,.........	within the sphere.		

In spheres of diamond and other substances of high refractive power, a refracted ray C*c* may fall so obliquely upon the inner surface of the sphere, that it would be totally reflected, and would therefore be carried round the surface of the sphere, without the possibility of making its exit. If the length of the refracted ray C*c* should cut off an arch which is an aliquot part of a circle, the ray would describe a regular polygon, being always reflected from the same points; but if it was not an aliquot part of a circle, the points of reflexion would vary in every revolution of the ray.

The following is the rule for finding the principal focus of a sphere, or its focus for parallel rays:—Divide the index of refraction by twice its excess above unity, and the quotient is the distance of the principal focus from the centre of the sphere.

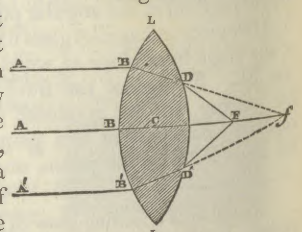
When the rays RC, RC, in place of falling on the sphere in directions parallel to the axis, or to one another, proceed from a near object, and always from a point in the axis RSE, their focus may be found by the very same method which we have already given. When the point from which the rays diverge is very distant, the focus of such rays will be a little farther from the sphere than F, and as the radiant point approaches to the sphere, the focus F will recede from it, as will be more fully explained when we treat of the progress of rays through lenses.

Refraction of Rays by Convex Lenses.

The action of an equally convex lens in refracting rays of light, is exactly the same as that of a sphere, with this difference only, that the two surfaces are brought nearer each other, and in consequence of this the ray refracted by the first surface falls upon the second surface, at a different point, and at a different angle, the effect of which is to produce a change in the position of the focus.

the Parallel rays.

Fig. 30.



Dioptrics.

Let LL be a double and equally convex lens of glass, a line Af passing through the centre C, or middle point of its greatest thickness, is called its axis. Let *parallel rays* AB, A′B′, fall upon the first surface, at the points B, B; these will be refracted in directions BD, B′D′, which will be determined by the method shewn in fig. 28. Had there been no second surface, these rays would have converged to a focus at f, but as they meet the second surface of the lens at D and D′, they will there be refracted, as shewn in fig. 28, for the sphere, so as take the directions DF, D′F′, and have their principal focus at F.

The following is the rule for finding the principal focus of a glass lens unequally convex:—Multiply the radius of the one surface by the radius of the other, and divide twice this product by the sum of the same radii.

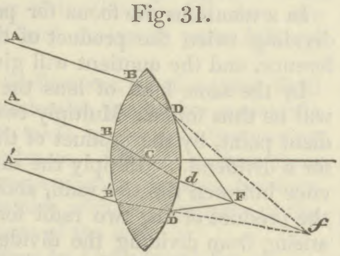
If the glass lens is equally convex, and has its index of refraction 1·500, the distance CF, or its principal focal distance, will be equal to the radius of any of its surfaces.

The following is the rule for finding the principal focal distance of a plano-convex lens of glass. When the convex side is exposed to parallel rays, the focal distance, reckoned from the plane side, will be equal to double the radius of the convex surface, diminished by two-thirds of the thickness of the lens. When the plane side of the lens is exposed to parallel rays, the distance of the focus from the convex side will be equal to twice the radius.

Oblique rays.

When the rays AB, AB are oblique to the axis, the middle ray AC passing through the centre C, will obviously suffer refraction at B, but as it falls upon the second surface at the same angle, it will be refracted a second time in an opposite direction, so that it will proceed in a direction df parallel to AB. The rays AB, AB will suffer refraction at the points B, B′, and also at the points D and D′, and it will be found by projection that they meet in a focus F in the axis $d\,f$.

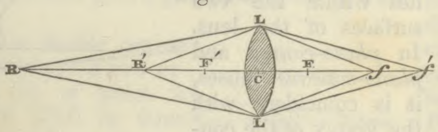
Fig. 31.



Diverging rays.

In the preceding case the parallel rays are supposed to issue from some very distant object; but if the object from which the rays proceed is near or not very distant from the lens, its focus will recede from the lens, in proportion as the object or point of divergence approaches to it. This fact scarcely requires to be proved, for it is manifest that as the radiant point approaches to the lens, the rays fall more and more obliquely on the first surface, and less and less obliquely on the second, so that the deviation produced by refraction is not sufficient to bring them to a focus so near the lens as the point F, in fig. 30. This will be better understood from fig. 32, where LL is a convex lens, whose focus for parallel rays is F. Let RL, RL be rays diverging from a candle or other body, at R, then, if we trace the refracted rays by the method already given in fig. 27, we shall find that they will meet at a point f, farther from the lens than F, and that if the point R advance to R′, the focus f will advance to f', and so on, the focus f' receding from the lens as R approaches to it. When the distance RC is equal to twice CF, or twice the principal focal distance, the distance of the focus f' from the lens will be equal to the distance of the radiant point from it, or Cf' will be equal to CR′. When R comes nearer C, f' goes rapidly away from it, and when R comes to F′, which is called the anterior focus, CF′ being equal to CF, the rays will be parallel, or what is the same thing, the focus f will have retired to an infinite distance. When R comes nearer to C than F′, the rays will diverge, after passing through the lens, as if they came from some point in front of the lens, and this point, or *virtual focus*, as it is called, will approach to the lens as R approaches it, in moving from F′ towards C. The points R and f, and R′ and f', are called *conjugate foci*, because it may be shewn that rays diverging from f will be refracted to R, and rays diverging from f' to R′. It is indeed a general truth in all the phenomena of refraction and reflexion, that if the refracted rays are supposed to be the incident ones, the incident rays will be the refracted ones; for the ray experiences the very same action in an inverse order, by retracing its path.

Fig. 32.



The following is the rule for finding the focus f, or the conjugate focal length of a convex lens of glass for diverging rays: Multiply twice the product of the radii of the two surfaces of the lens, by the distance of the radiant point or RC, for a *dividend*. Multiply the sum of the two radii by the same distance RC, and from this product subtract twice the product of the radii for a divisor. The quotient of the dividend divided by the divisor will be the focal distance Cf required.

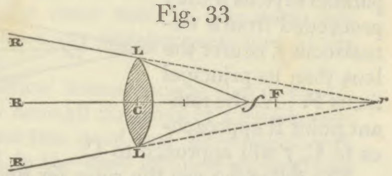
When the lens is *equally-convex*, multiply the distance of the radiant point RC, by the radius of the surfaces, and divide that product by the difference between the same distance and the radius, and the quotient will be the focal distance Cf required.

If the lens is *plano-convex*, divide twice the product of the distance of the radiant point RC, multiplied by the radius of the convex surface, by the difference between that distance and twice the radius, and the quotient will be the distance of the focus from the centre of the lens.

Converging rays.

When converging rays fall upon a convex lens, they are always refracted to a point between the lens and their point of convergence. Let RL, RL, be rays converging to any point r, behind the lens LL, it is very evident that refraction must always make them cross the axis RCr of the lens somewhere between r and the lens, and always between the principal focus F and the lens. The exact point may be found by the methods already given. As the point of convergence r recedes from the lens, the focus f will approach to the principal focus F, and when r is infinitely distant, the rays RL, RL, become parallel, and f will coincide with F. When r approaches to C, f will also approach to it.

Fig. 33



The focus of a double convex glass lens, when its thickness is small, for converging rays may be found by the following rule: Multiply twice the product of the radii of the two surfaces by the distance rC of the point of convergence for a *dividend*. Multiply the sum of the two radii by the same distance rC, and add to this product twice the product of the radii for a *divisor*. The quotient obtained by dividing the above dividend by this divisor, will be the focal distance fC required.

When the lens is *equally*-convex, multiply the distance rC by the radius of the surfaces, and divide that product by the sum of the same distance and the radius, and the quotient will give the focal distance fC required.

In *plano-convex* lenses we must divide twice the product of the distance rC multiplied by the radius of the convex surface, by the sum of that distance and twice the radius, and the quotient will give the focal distance required.

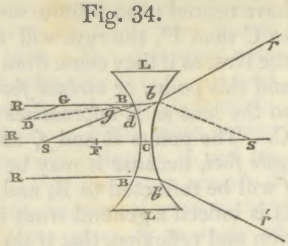
Refraction of Rays by Concave Glasses.

In order to shew how to find the refracted ray when the

Dioptrics.

light is incident on a *concave* surface, let LL be a double and equally concave lens of glass, and RB, R′B′ two rays parallel and equidistant from the axis RC of the lens. From a scale on which RB is 1·5, take BG equal to 1, and from G draw GD parallel to SB, the radius, and consequently perpendicular to the first concave surface of the lens. Make BD equal to BR, and through D and B draw B*b*, which will be the ray refracted by the first surface. On a scale where *b*B is 1, make *b*B*g* equal to 1·5. From *g* draw *gd* parallel to *bs*, the radius of the second surface, and consequently perpendicular to that surface at *b*. Make *bd* equal to *b*B, and through *b* draw *dbr*, *br* will be the ray refracted by the second surface. In like manner the other ray RB will be refracted by the first surface in the direction B′*b*′, and the two refracted rays *br*, *b′r′* will diverge as if they had proceeded from a point F, found by continuing *br*, *b′r′* backwards, which is called the virtual focus of the concave lens, LL.

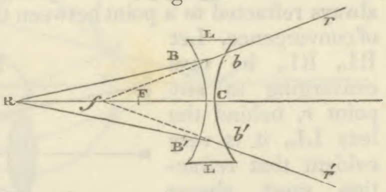
Fig. 34.



If we trace *oblique parallel* rays through a double concave lens in the same manner as we have done for a convex one in fig. 31, we shall find that they will be refracted as if they diverged from a focus in the axis or ray which passes through the centre of the lens. The rules for finding the virtual focus of paralell rays refracted by a double or plano-concave lens, are the same as for convex lenses.

When *diverging* rays RB, RB, fall upon a concave lens LL, they will be refracted in lines *br*, *b′r′*, more divergent than parallel rays, as if they proceeded from a virtual focus *f*, nearer the lens than its principal focus F. As the radiant point R approaches to C, *f* will approach to C.

Fig. 35.

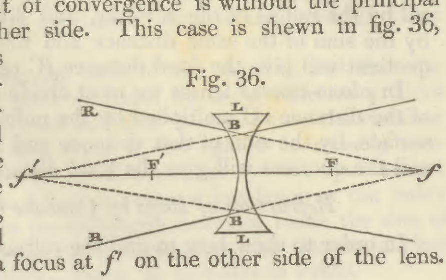


The following are the rules for finding the virtual focus of a concave lens of glass for diverging rays. Multiply twice the product of the radii by the distance RC of the radiant point R for a *dividend*. Multiply the sum of the radii by the distance RC, and add to this twice the product of the radii for a *divisor*. Divide the dividend by the divisor, and the quotient will be the virtual conjugate focal distance *f*C. If the lens is *equally-concave*, multiply the distance of the radiant point R by the radius, and divide the product by the sum and the same distance and the radius, and the quotient will be the virtual focal distance required.

If the lens is a *plano-concave* one, multiply twice the radius by the distance of the radiant point, and divide this product by the sum of the same distance and twice the radius, and the quotient will be the virtual focal distance.

When *converging rays* fall upon a concave lens, their virtual focus will be without the principal focus on one side, if the point of convergence is without the principal focus on the other side. This case is shewn in fig. 36, where the rays RB, R′B′, converging to *f*, without the principal focus F, will be refracted in the direction *br*, *b′r′*, as if they had diverged from a focus at *f′* on the other side of the lens.

Fig. 36.



When *f*C is equal to twice the principal focal distance CF, the virtual focus of divergence *f* will be at the same distance on the left hand of C as the point of convergence *f′* is distant on the right hand. When *f* approaches the lens on the right hand, the virtual focus *f* will recede from it on the left. When *f* reaches F, the virtual focus will be infinitely distant, or the refracted rays will be parallel; and when *f* advances from F to the lens, the refracted rays will converge on the right hand of the lens, and the focus will advance towards the lens, as the point of convergence advances towards it.

The rule for finding the conjugate focus of a converging beam, for a doubly concave lens, is the same as that for diverging rays in a doubly convex lens. If the lens is plano-concave, the rule is the same as for diverging rays falling upon a plano-convex lens.

Refraction of Rays through Meniscuses, and Concavo-Convex Lenses.

It would be quite unprofitable to trace the progress of different rays through these various forms of glasses, both because they are but little used, and because the very same methods which are applicable to convex and concave surfaces, are applicable also to them. When used by themselves and for ordinary purposes, these lenses are inferior to the common convex and concave lenses, and therefore are seldom met with. We shall therefore content ourselves with giving the rules for finding their foci.

In a meniscus the focus for parallel rays is obtained by dividing twice the product of the two radii by their difference, and the quotient will give the focal distance.

In the same kind of lens the focus for diverging rays will be thus found: Multiply twice the distance of the radiant point, by the product of the radii of the two surfaces, for a dividend. Multiply the same distance by the difference between the two radii, and to their product add twice the product of the two radii for a divisor. The quotient arising from dividing the dividend by the divisor, will be the focal distance of the meniscus. This rule will answer also for converging rays.

In *concavo-convex* lenses the very same rules will apply, but the rays have a virtual focus in front of the lens, as in concave lenses.

In treating of the passage of oblique rays through a double convex glass, as shewn in fig. 31, we have stated that there is a point C, called the centre of the lens, through which the ray that passes suffers the same refraction at both surfaces, or emerges parallel to its original direction. In equally double convex lenses, this centre C is accurately in the middle part of the thickness of the lens; but in other forms of lenses it is not. Hence it is necessary to point out the method of finding this centre. In *double convex* or *concave lenses*, the centre C, see fig. 31, 37, and 38, lies within the two surfaces of the lens. In *plano-convex* and *plano-concave* lenses, it is coincident with the vertex of the convex or concave surfaces, and in *meniscuses* and *concavo-convex lenses* it lies without the thickness of the lens, and nearest to the surface which has the greatest curvature. Let R, *r*, figs. 37—40, be the centres

Fig. 37.

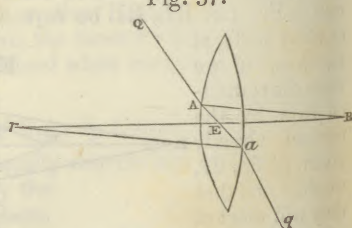


Fig. 38.

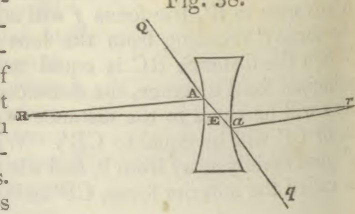

Dioptrics.

of the convex and concave surfaces of the lenses, and R*E*r, fig. 37, 38, or R*r*E, fig. 39, 40 are their axes. Taking any point A in one surface, draw RA, and parallel to this draw *ra*, which will cut the other surface of the lens in *a*. Join A*a*, and continue it till it meets the axis RER in same point E; this point E is called the centre of the lens, because every ray that passes through it will have its incident and emergent parts parallel, such as QA, and *qa*. From the similarity of the triangles REA, *r*E*a*, and the composition and division of ratios, we have $RA \mp ra : ra = RE \mp rE$ (or R*r*) : *r*E, hence *r*E must be invariable like the other lines, and on whatever point the parallel radii RA, *ra*, are drawn, the line A*a* must cut the axis R*r* in the same point E. If we suppose the ray A*a* to pass out of the lens in both directions, it will suffer the same quantity of refraction in opposite directions, because the angles of incidence *a*AR, A*ar*, are equal. Hence the incident and emergent parts AQ, *aq*, will be parallel.

Fig. 39.

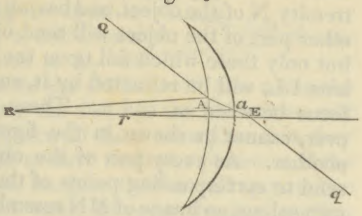

Fig. 40.

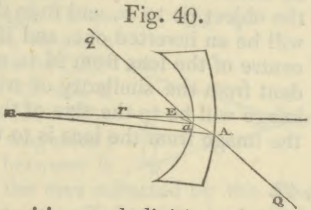


When the lens is small in diameter, or of a great focal length, or its thickness inconsiderable from other causes, the path of the ray QA*aq*, may be taken in a straight line passing through the centre E of the lenses. This is evident from the circumstance that the perpendicular distance between the lines AQ, *aq* diminishes both with the obliquity of the incident ray, and the thickness of the lens.

On the Refraction of Rays by Cylindrical Lenses.

Refraction by cylindrical lenses.

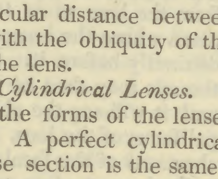
Cylindrical lenses may have all the forms of the lenses which we have already described. A perfect cylindrical lens corresponds with a sphere whose section is the same; a plano-convex cylinder has its section similar to a plano-convex lens of the same dimensions; and a meniscus cylinder has one of the cylindrical surfaces convex and another concave.

In all these cases the curved surfaces are cylindrical; that is, circular in one direction, and rectilineal in another; but we may combine a spherical surface either convex or concave, with a cylindrical surface either convex or concave, and thus produce cylindro-spherical lenses, an ingenious application of which to vision was made by Mr. Airy, for the purpose of remedying a defect in his own eye.

This class of lenses, therefore, whether entirely cylindrical, or cylindro-spherical, having been found of real use both in matters of science, and for the purposes of vision, it becomes of consequence to give a general account of their properties.

Let LLL′L′ be a double convex cylindrical lens, composed of two cylindrical surfaces, one of which is LLL′L′. Then if RRR be three parallel and horizontal rays passing through the thinnest portion of the upper part of the lens, it is obvious that they will be refracted to a focus at F, at the same distance from the lens, as in an ordinary lens. In like manner the rays R′R′R′ falling upon the lowest portion of the lens will have their focus at F′. Every intermediate portion of the lens will have a similar focus somewhere in the line FF′, and if we suppose all the rays to proceed from a distant object, such as the sun, there will be an image of the sun, or a luminous focus in every point of the line FF′, and FF′ will be a brilliant line of light.

Fig. 41.



This property of a cylindrical lens to form a bright line of light has been ingeniously applied by Captain Kater in the construction of his azimuth compass, which we have described in our article MAGNETISM, vol. xiii. p. 765.

In cylindrical lenses diverging and converging rays will have the same foci as in common and concave lenses of the same curvature; and therefore the rules for finding their foci are applicable also to them.

Cylindrical lenses have been recently applied by Sir David Brewster for improving the vision of objects that are rectilineal, such as the defective lines in the solar spectrum. When these lines are not visible, or are very imperfectly visible, on account of the imperfections of the telescope, the application of a cylindrical lens, either solid or fluid, renders them more visible when the axis of the cylinder or cylindrical surface is accurately perpendicular to the lines. A prism has a similar effect. Both of them act in filling up the irregularities of the edges of the line by a succession of images of other parts of the line. If we look, for example, at a screw nail, or a twisted or rough rope, through a prism or cylinder, whose length is perpendicular to the screw or rope, the edges of both will be as smooth as if they were polished cylinders.

A patent was taken out several years ago by a Parisian artist for a transverse cylindrical lens similar to that shewn in fig. 22 O; which differs from the cylindrical lens in fig. 41 in this, that the second cylindrical surface has the axis of the cylinder of which it is a part, perpendicular to the axis of the cylinder of which the first surface is a part. The effect of this combination is *exactly* equivalent to a plano-convex glass of the same radii of curvature, and therefore it does not possess any superior properties, as was believed by its inventor.

If we cross two cylindrical lenses, such as that in fig. 41, at right angles, we shall have all the effect of a double convex lens. Or if we cross two good test tubes filled with water or any other fluid, in the same manner, we shall also obtain a rude imitation of the effect of a spherical lens, which may answer for the common purposes of a microscope.

Mr. Airy's sphero-cylindrical spectacles.

The application of a cylindro-spherical lens by Mr. Airy to the purpose of remedying imperfect vision in his own eye deserves to be more particularly noticed. He found that his eye refracted rays to a nearer or shorter focus in a vertical than in a horizontal plane,[1] so that his eye was completely useless. Hence he concluded that the curvature of his cornea was greater in a vertical than in a horizontal plane, and he ingeniously proposed to correct this defect by cylindrical refraction. As the eye was shortsighted, he required concave surfaces to correct the general defect of a too convex cornea. He therefore had a lens constructed, which was doubly concave, one of the surfaces being spherically concave, and the other cylindrically concave, and of such a curvature as to bring to the same point the vertical and horizontal foci of the cornea. An artist of the name of Fuller, at Ipswich, constructed for Mr. Airy lenses of the proper dimensions, which enabled him to read the smallest print at a considerable distance with his defective eye, as well as he could do with the other. He found that vision was most distinct when the cylindrical surface was turned from the eye, and he placed the lens as near the eye as possible. There is another application of cylindrical lenses which we believe has not hitherto been made. In

[1] This was the case also in Dr. Thomas Young's eye, but it did not injure his vision. *El. Nat. Phil.* vol. ii. pp. 578, 9.

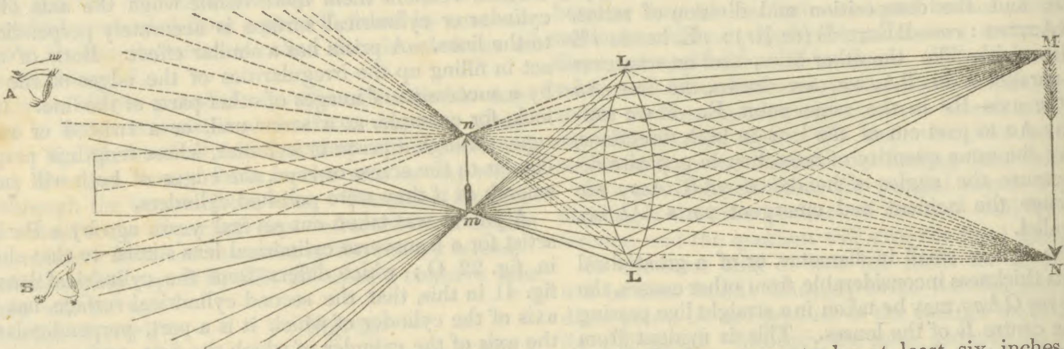
Dioptrics. all preparations of natural history, objects which are generally preserved in cylindrical bottles or vessels containing fluids, the objects are always seen distorted, being magnified to the greatest extent in a plane perpendicular to the length or axis of the cylinder, while in a rectangular direction, the object is not magnified at all. In order to see the objects of their true shape, and have them equally magnified in all directions, a cylindrical lens of a suitable focus should be employed, so that the axis of the cylinder may be at right angles to the cylindrical axis of the vessel.

Sect. III.—*On the Formation of Images by Lenses, and on the vision of objects through them.*

In the preceding section we have treated of the formation of images by rays transmitted through small apertures, and have considered the formation of images by reflecting surfaces.

In order to explain the formation of images by convex lenses, whether double, or plano-convex, or meniscuses, let LL be a convex lens, MN an object farther from it than its principal focus. Let MLL be a cone of divergent rays proceeding from M, and having their focus at *m* behind the lens; and NLL another similar cone from the other extremity N of the object, and having their focus at *n*. Every other part of the object will send out rays in all directions; but only those which fall upon the circular surface of the lens LL, will be refracted by it, and they will all have their focus between *m* and *n*. These refracted pencils, however, cannot be shewn in the figure without crossing one another. As every part of the object MN, will therefore send to corresponding points of the image *mn* rays of their own colour, an image of MN resembling it in all respects will be formed at *mn*, and as the rays from the upper part M of the object go to *m*, and from the lower part to *n*, this image will be an inverted one, and if we draw lines through the centre of the lens from M to *m*, and N to *n*, it will be evident from the similarity of triangles that the size of the image will be to the size of the object, as the distance of the image from the lens is to the distance of the object.

Fig. 42.



If we place the eye behind this image *mn*, we do not see it suspended in the air at *mn*, but it appears as if it were in front of the lens. That the image, however, is formed at *mn*, may be proved by viewing it on smoke raised at that place, or on a piece of ground glass, or semi-transparent paper; or if we bring the eye in front, we shall see it distinctly painted on any white ground, such as a piece of white paper. We shall suppose it, however, to be seen on smoke by the eye placed behind it at A or B. It will be seen exactly at *mn*, as if it were a real object; and in order to see it distinctly, the eye must view it at the same distance as it views other objects, and it may be viewed as any other object is, through a pair of spectacles or a magnifying glass.

As all the rays from M, N cross each other at the points *m*, *n* of the image, the very same rays radiate from those points that radiated from M, N, and consequently the very same effect must be produced in the eye as if these rays proceeded from a real object at *mn*. Hence by placing another convex lens at a proper distance behind *mn*, a distance greater than its principal focus, we may form another image of this image, in the conjugate focus of the second lens.

If we wish to form a magnified image of an object by any lens, we have only to place the object nearer the lens, and it follows from the rules for conjugate foci that the image will increase. If MN, for example, is brought nearer LL, the image *mn* will recede from the lens, and increase in size. When ML is equal to twice the principal focal distance of the lens, the distance of the image *m*L, and the size of the image will be the same as that of the object MN. If MN comes still nearer the lens, *mn* will recede still farther, and continue to increase in size till it becomes infinitely large and infinitely distant. When this happens, the rays which form it will have become parallel. If during all these changes the eye is withdrawn from the lens so as to be at least six inches behind the place where the image is formed, it will observe the image distinctly before it. But when the rays become parallel, the eye may then be placed immediately behind the lens, and it will see the object distinctly in the anterior principal focus of the lens, and magnified in proportion to the shortness of the focal distance of the lens.

In the preceding paragraphs, we have described the principles of the *camera obscura*, the *compound microscope*, and the operation of the *single microscope*. When the image *mn* is distinctly formed on paper, the lens LL acts as in the *camera obscura*, painting all objects before it in their natural colours, in their just proportions, and with all their movements, on a white ground placed behind it. When the image *mn* has become greater than the object MN, by the advance of the latter to the lens, the eye views this magnified picture, and the effect is the same as in the *compound microscope*, whose object-glass is LL, and whose eye-glass has a focal distance equal to that of the eye. When the image is infinitely distant, and the rays enter the eye parallel, the object being then in the anterior principal focus of the lens LL, and the eye behind it, the lens is then acting as a *single microscope*.

When objects are within our reach, such as microscopic objects, or near objects presented before a camera obscura, it is always in our power to illuminate them with artificial light, and thus make dark objects give brighter images; but when this cannot be done, in consequence of the objects being out of our reach, we can increase the brightness of the image by increasing the area or superficies of the lens. If the area of the lens LL, for example, were doubled, it would collect twice the quantity of rays that flow from every point of an object, and concentrate them at the corresponding points of the image *mn*.

In order to understand the principle of the *telescope* and *single microscope*, we must be acquainted with what is

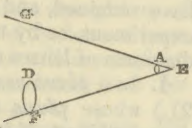
Dioptrics.

called the *apparent magnitudes* of objects. If we hold a sixpence A at the distance of six or eight inches from the eye E, then it will exactly cover or appear equal to a shilling placed at B, a half-crown placed at C, and a crown at D. If we remove the sixpence A, the shilling will just cover the half-crown. If we remove the shilling, the half-crown will just cover the crown. Hence all these coins placed as they are in the figure, are said to have to an eye placed at E the same apparent magnitude, because they are all seen under the same angle DEF, and would all cover the same portion of the sky, or of any distant object.

Fig. 43.

If the sixpence A is brought thrice as near the eye E as in fig. 44, its angle of apparent magnitude will now be GEF thrice as great as DEF, fig. 43, and it will appear thrice as large as DF. The sixpence has therefore been magnified; and if we interpose a lens between it and the eye, so as to make the rays refracted by the lens parallel, it will appear distinctly *magnified*, and the lens which we interpose will be a single microscope.

Fig. 44.



Objects within our reach, and capable of being placed where we please, may be therefore magnified to any extent, by placing them very near the eye, and in the anterior focus of a small convex glass, which, by making the diverging rays parallel, render the object as distinctly seen under a great angle, as if it were a large object placed at a distance, and subtending the same angle at the eye.

But when objects are at a distance, and beyond our reach, such as remote terrestrial objects, and the planets and stars, we can magnify them, or represent them to our eye under a greater angle of apparent magnitude, by a different principle. If the object is the dial-plate of a clock, at the distance of 12,000 feet, we place a lens whose focal distance is *six* feet, in the end of a tube about six feet long, and having directed it to the dial-plate, a distinct inverted image of the dial-plate will be formed in the focus of the lens, at a distance of six feet from it, and if we view this image with our eye placed six inches behind it, we shall see the image of the dial-plate distinct and magnified. Now, as the distance of the dial-plate is 12,000 feet, and that of the image only *six* feet from the lens, the image will be $\frac{12,000}{6}$, or 2000 times smaller in diameter than the object, not in apparent magnitude, but by real measurement; and if we were to take the image and place it beside the dial-plate, and view them both at the distance of 12,000 feet, their apparent magnitudes would, like their real magnitudes, be in the proportion of 2000 to 1. But the image is fortunately within our reach, and we can do with it what we choose. Let us first view it with the naked eye, which, generally speaking, sees objects most distinctly at a distance of six inches, and as we see it at the distance of six inches, it will appear as much greater as it would have done at the distance of 12,000 feet, as 12,000 feet is to six inches, or as 24,000 is to 1. Hence it follows, that though the image is diminished in the focus of the lens 2000 times, yet it is magnified from its proximity to the eye 24,000 times, that is, it is magnified on the whole $\frac{24,000}{2000}$, or *twelve* times. Now, this magnifying effect will be found under all circumstances to be equal to the focal length of the lens employed, divided by the focal distance of the eye, or the distance at which it sees small objects most distinctly, which is six inches, that is, in the present case $\frac{\text{six feet}}{\text{six inches}}$, or $\frac{72 \text{ inches}}{6 \text{ inches}}$, or *twelve* times. A short-sighted person, whose eyes have a focus of only three inches, would be able to see the same image of the dial-plate at the distance of *three* inches, and in his case the magnified effect would be $\frac{72 \text{ inches}}{3 \text{ inches}}$, or 24 times, and an old person, or one whose eyes were long-sighted, so as not to be able to see objects distinctly, nearer than 12 inches, would see the dial-plate magnified only six times. But both these persons could put on highly magnifying spectacles, so as to see the image at very short distances, or what is the same thing, to look at the image of the dial-plate through a magnifying glass, which would enable them to see it at the distance of one inch. In this case the magnifying effect would be $\frac{72}{1}$, or 72 times.

Telescopes

But the instrument which we have now fitted up is precisely a telescope, the large lens being its object-glass, and the small one used by the observer its eye-glass, and hence the magnifying power of such an instrument is always equal to the focal length of the object-glass divided by the focal length of the eye-glass. The image formed by such a telescope is inverted, which is of no consequence when we look at the heavenly bodies, and it is therefore called an *astronomical telescope;* but in looking at the dial-plate, and at terrestrial objects, the inversion would be disagreeable, and it is therefore usual to make the image erect, by using either a *concave* eye-glass, or three or more convex eye-glasses. In the former case it is called the *Galilean telescope*, and in the latter a *terrestrial telescope.*

When the distance of the object is not very great, or when the focal length of the lens bears a considerable proportion to the distance of the object, the magnifying power of a lens, when the eye views the image formed by the lens at the distance of six inches, is the following. Subtract the focal distance of the lens in feet from the distance between the image and the object, and divide the remainder by the same focal distance. By this quotient divide twice the distance of the object in feet, and the quotient will express the magnifying power, or the number of times that the object has been increased in apparent magnitude by the lens.

The very same observations apply to images formed by concave mirrors, and hence a single concave mirror becomes the simplest form of the reflecting telescope, the eye viewing the image which it forms. In the case of such images the body or the head of the observer must be placed between the object and the image, so that in order to use a single concave mirror, we must either make the mirror so large that the observer's head will not obstruct all the light, or we must make the reflexion a little obliquely, or, what is done in practice, we must by means of a small plane mirror or a prism reflect or refract the rays to one side, so as to allow the observer to look at the image formed by the concave mirror, without obstructing the rays in their passage from the object to the mirror, the quantity obstructed by the plane mirror or prism being too small to do any injury. If we view the image through a convex lens, so as to magnify it still more, the mirror and the lens will constitute a *reflecting telescope.*

PART III. ON SPHERICAL ABERRATION AND CAUSTIC CURVES.

Spherical aberration.

The rules which we have already given for finding the foci of lenses and mirrors, are strictly applicable only to rays that pass near the axis of the lenses and mirrors; and this may be readily proved by the method of finding the refracted and reflecting ray which we have explained and used.

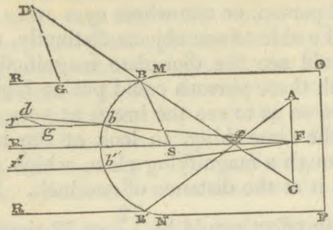
SECT I.—*On Spherical Aberration of Lenses.*

In order to prove and illustrate the preceding truth, we shall suppose parallel rays to be incident on a mass of glass MNOP, in which there is only refraction at its first surface, and we do this both to avoid the confusion of lines, and because it is perfectly sufficient for the purpose of explanation. Let RS be the axis of the spherical surface MN, passing

Spherical aberration.

through S, its centre of curvature; and if we consider it a ray, also, it will go on to F without any refraction. Let RB be a ray falling on the refracting surface at a distance from the axis RS, and parallel to it. From the point of incidence draw BS, which will be perpendicular to the surface at B, and take BG three fourths of BR, BG being to BR as 1 is to 1·500, the index of refraction. From G draw GD parallel to BS, and making BD equal to BR, through the points D and B, draw B*f*C for the refracted ray. Do the very same thing for the ray RB′ falling on the point B′, and parallel to RS, and equidistant from it, and B*f*A will be the refracted ray.

Fig. 45.



If we now take two rays *rb*, *r′b′* near the axis, and parallel to and equidistant from it, and apply the same method of projection to them, we shall find the refracted rays to be *b*F, *b′*F crossing the axis, and converging at a point F, more remote from the refracting surface than *f*. If we draw through F a line AEC, perpendicular to the axis, then A and C being the points where the marginal or most remote rays which fall on the surface MN, and F being the focus of those nearest the axis, the distance *f*F is called the *longitudinal spherical aberration*, and AC the *lateral spherical aberration* of the lens.

These results may be obtained experimentally by covering up with a circle of black paper, all the central parts of the spherical surface, leaving a clear marginal ring corresponding with BB′. If the surface thus limited is exposed to the solar rays, we shall find a pretty distinct picture or image of the sun formed at *f*, which, from a cause which we shall soon explain, will be highly coloured at the edges. If we now remove the black circle from the surface MN, and cover the outside surface with black paper, excepting a small opening in the vertex of the lens, where the axis RS cuts it, and expose the lens to the sun's rays, we shall find the image of the sun distinct at F, and it will be less coloured than the image formed at *f* from another cause.

If we now expose successive rings of the surface MN to the sun's light, shutting up all the rest of the lens, we shall find that the ring nearest the axis will have its focus near *f*, between *f* and F; the second ring, its focus still nearer F; the third, its focus still nearer F; and so on, till the last ring will give its image of the sun close to F. Hence it follows, that there will be distinct images of the sun formed by each ring, and occupying the whole space *f*F; and, therefore, if we expose the whole surface MN to the solar rays, the image of the sun must be extremely confused and indistinct; and if received upon a sheet of white paper placed at AC, it will consist of a bright disc at F, surrounded with a broad halo of light, becoming fainter and fainter towards A and C.[1]

As this is true of every spherical surface whatever, it follows, that every image formed by a spherical surface or lens, and every object seen through it, must be indistinct, from the confusion of rays produced by spherical aberration. As this indistinctness increases with the aperture of the lens, or the distance of the marginal rays from the axis, we may remove it to a certain degree by limiting the aperture, or using smaller lenses; but excepting in the case of the sun or any highly luminous body, this diminution of the aperture would injure vision, from the want of light, especially in microscopes and telescopes; and hence it becomes an object of the highest importance in optics, and it is one which has occupied much attention, to discover methods of diminishing or correcting the spherical aberration of lenses.

Spheric aberratio

Philosophers have, therefore, been led to calculate with accuracy the amount of spherical aberration in lenses of different forms, and having different sides exposed to the incident rays. The following are the results which they have obtained, and they may be readily verified either by experiment, or by tracing the refracted rays through large diagrams of lenses of different shapes.

Forms lenses least a greate aberrat

1. In a *plano-convex* lens, (such as that shewn at E, fig. 21.) whose *plane side is turned to parallel rays*, or to distant objects, if it is intended to form an image of them in its focus; or with its plane side turned to the eye, if it is to be employed as a single microscope or magnifier, the *spherical aberration* is $4\frac{1}{2}$ *times its thickness*, or the *greatest* that can be obtained from it. This is called its *worst* position.

2. In a *plano-convex* lens, whose *convex side is turned to parallel rays*, the spherical aberration is only $1\frac{17}{100}$ths of its thickness, or the *least* that can be obtained from it. This is called its *best* position.

3. In *double convex lenses* with equal convexities, the spherical aberration is $1\frac{67}{1000}$ths of their thickness, greater than that of a plano-convex lens in its best position.

4. In *double convex lenses*, having their radii as 2 to 5, the spherical aberration will be the same as in a *plano-convex* lens in its *worst position*, if the flattest side, or that which has its radius 5, is turned towards parallel rays; and it will be the same as that of a *plano-convex lens* in its *best position*, if the surface whose radius is 2 is turned to parallel rays.

5. The *lens of least spherical aberration* is a double convex one, the radii of whose surfaces are as 1 to 6, having the surface whose radius is 1 *turned towards parallel rays*. In this, which is its best position, the aberration is only $1\frac{7}{100}$ths of its thickness. But if the side with the radius 6 is turned towards parallel rays, the aberration will be $3\frac{45}{100}$ths of its thickness.

If we determine the virtual focus of the central and marginal rays for a concave surface, as in fig. 45, we shall find that the spherical aberration is exactly the same for *concave* as for *convex* lenses; and hence, all the preceding results are equally applicable to them.

If we suppose that the lens of least spherical aberration, as in art. 5, has an aberration expressed by unity, the comparative aberrations of other lenses will be as follows:

Double convex or concave with radii as 1 to 6, in *best position*....	1·000
Plano-convex or concave in *best position*....	1·081
Double equi-convex or equi-concave....	1·561
Plano-convex or concave in *worst position*....	4·206

[1] "The effect of aberration," says Sir John Herschel, "may be very prettily exhibited by covering a large convex lens with a paper screen full of small round holes, regularly disposed, and exposing it to the sun, receiving the converged rays on a white paper behind the lens, which should be first placed very near it, and then gradually withdrawn. The pencils which passed through the holes will form spots on the screen, and their disposition will become more and more unequal over the surface, as the screen is farther removed; those at the circumference becoming crowded together before the central ones. The manner in which the several spots corresponding to central rays blend together into an image at the focus, and those formed by the exterior ones are scattered round it, gives us a very good idea of the variation of density of the rays in the circle of aberration at or near the principal focus; and if the white screen be waved rapidly to and fro in the cone of rays, so as to pass over the focus at each oscillation, the whole cone will be seen as a solid figure in the air, and the place of the circle of least aberration will become evident to the eye, forming altogether a very pleasing and instructive experiment." *Treatise on Light*, § 317.

As a general rule for all lenses already made, and whose focus it is inconvenient to alter, the *most convex surface* should always be placed *towards parallel rays* when the lenses are used singly.

The preceding results are calculated on the supposition, that the lens is made of glass, whose index of refraction is 1·500; but the numerical results vary greatly when we use transparent media of higher and lower refractive powers. When the index of refraction, for example, is 1·6861, which is nearly that of some of the metallic glasses, and of several precious stones, and of sulphuret of carbon nearly, the lens of *least spherical aberration*, is not one which has its radii as 1 to 6, but one which is *plano-convex;* and when we come to higher refractive powers, such as those of *sapphire, ruby, garnet* and *diamond*, of which lenses are now made for microscopes, and ought to be made for the eye-glasses of powerful telescopes, one of the surfaces of the lens of least spherical aberration must be concave. This will be seen from the following results which we have calculated from Sir John Herschel's Formula,[1] viz. $\frac{R''}{R'}=\frac{2\mu^2-\mu-4}{2\mu^2+\mu}$ where R″ and R′ are the radii of the surfaces of the lens of least spherical aberration, and μ the index of refraction.[2]

	Index of Refraction.	Ratio.
Vacuum	1·000...1	to 1·00 equi-convex.
Tabasheer	1·100...1	to 1·31
New fluid in amethyst	1·111...1	to 1·35
Second do. in topaz	1·200...1	to 1·76
Ice	1·300...1	to 2·43
—— Water	1·3368..1	to 2·77
Cryolite	1·350...1	to 2·93
Fluor spar	1·400...1	to 3·60
Plate glass	1·500...1	to 6·00
Quartz, Topaz	1·600...1	to 14·00
Chrysolite	1·686...1	to infinity, plano-convex.
Sulphuret of carbon	1·700...1	to —93 meniscus.
Garnet, Ruby	1·800...1	to —12
Glass—lead 2½, flint 1	1·900...1	to —7
Zircon	2·000...1	to —5
Diamond, Octohedrite	2·500...1	to —2·5
Chromate of lead	3·000...1	to —2·1
	3·500...1	to —1·6
	4·000...1	to —1·5 equal radii.
	infinite 1	to —1

But it is not merely the curvature of the lens of least aberration that changes its character and its magnitude,—the aberration itself suffers a very great variation. This will appear from the table already referred to in our article Microscope; but we shall repeat that part of it which shews the amount of this change of the aberration, as the index of refraction changes from 1·4 to 2·0.

	Index of refraction.	Spherical aberration when least in parts of the thickness of the lens, which is supposed 1.[3]
Fluor spar	1·4	1·096
Glass	1·5	1·071
Quartz	1·6	0·933
Epidote	1·7	0·666
Sapphire	1·8	0.357
Sulphate of Lead	1·9	0·166
Zircon	2·0	0·062

In the case of diamond the aberration must be next to nothing; but in order to obtain this great advantage, its second surface must be very concave, which diminishes greatly its magnifying power. We have no doubt that artificial glasses or other solids will yet be made by art, and that mineral bodies will be discovered which will have such a high refractive power, as to enable opticians to remove almost wholly the spherical aberration of single lenses.

Spherical aberration.

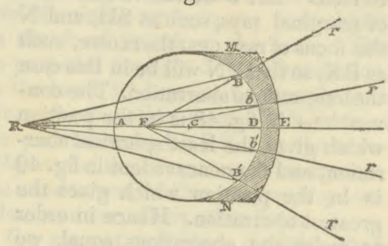
Aberration of rays not parallel.

Hitherto we have spoken only of the aberration of parallel rays, the effect of which is invariably to shorten the focus of the marginal or exterior rays; but when the incident rays converge or diverge, the aberration diminishes, and the focus of the marginal rays continues to be nearer the surface than that of central rays, till the focus of convergence or divergence comes up to *two particular points in the axis*, at the first of which, as will be presently seen, the aberration disappears, and at the second of which, namely, the focus of parallel rays in the convex side, it is infinite. When the focus of convergence or divergence is situated between these points, the effect of aberration is to lengthen the focus of marginal rays, and shorten that of central rays, the focal distance of the latter being now shorter than that of the former. These results are true for all curvatures and all indices of refraction.[4]

Sir John Herschel has given the following general rule for all double convex or concave lenses, and for all meniscuses and concavo-convex lenses in which the sum of the curvatures of their surfaces is greater than $\sqrt{2\mu+3\mu^2}$ times their difference, (μ being their index of refraction.) *The effect of aberration will be to throw the focus of marginal rays more* TOWARDS the incident light *than that of central ones, when the lens is of a positive character, or makes parallel rays converge; but more* FROM *the incident light if of a negative character, or if it cause parallel rays to diverge.*[5]

We have mentioned above, that there is a point in the axis, at which rays which diverge from it, and fall upon a concave surface, will have no spherical aberration. This will be understood from fig. 46, where BB′ is the first concave surface of a medium, C its centre, RCD its axis, and A a point in the spherical surface, where it meets the axis beyond the centre C. If we take two points R, F, such that RC is equal to the radius AC of the surface multiplied by the index of refraction, or RA to AF as the index of refraction is to unity, then all rays diverging from R, whether marginal or central, and falling upon the concave surface BDB′, will be refracted at BB′ in directions Br, B′r, which will proceed from the virtual focus F without any spherical aberration. This may be readily proved by the projection of the rays. Hence if upon F as a centre with any radius FE greater than FD, we describe a circle MEN, we shall have the second surface of a concavo-convex lens, which will be entirely free of spherical aberration. This is evident, as the rays refracted by the first surface BDB′ fall perpendicularly on the second surface, and suffer therefore no refraction.

Fig. 46.



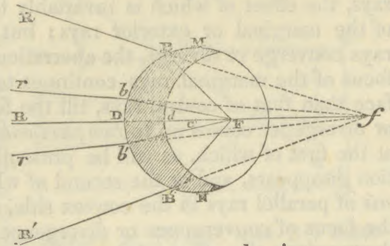
As there is a *concavo-convex lens* without aberration, for rays diverging from one point of its axis r, so there is a *meniscus* without aberration for rays converging to a particular point in its axis. Let RB, R′B′ be rays converging to a point f in the axis RCf of a convex refracting surface BDB′, whose centre is C. If we take fc, so that it is to the radius CD as the index of refraction is to unity, then it may be shewn by projection or calculation that the refracted rays RB, rb, whether marginal or central, will be refracted in lines BF, bf having the same focus F without any spherical aberration. Hence if with F as a centre we describe

[1] *Phil. Trans.*
[2] See our article Microscope for a table of the results obtained by Mr. Coddington, from indices of refraction from 1·4 up to 2·0.
[3] These aberrations are computed by Mr. Coddington.
[4] Sir John Herschel's *Treatise on Light*, § 288.
[5] *Id.* 299.

Spherical aberration.

any circle, having its radius Fd less than FD, we shall have the second or concave surface of a meniscus, which will have no aberration, because the rays BF, bF will pass through that surface perpendicularly, and suffer no refraction.

Fig. 47.



Owing to the injurious effect of spherical aberration on the performance of telescopes and compound microscopes, philosophers have sought to correct the spherical aberration of convex lenses, by the opposite aberration of concave ones. We have already given drawings[1] of three doublets without spherical aberration, according to the calculations of Sir John Herschel; and we shall now give an account of the method used by Dr. Blair of correcting the spherical aberration in his compound object-glasses, and as they possess some historical interest, we shall give the same diagrams which he employed. Let AB, fig. 48, represent a convex lens receiving a pencil of diverging rays from the object S, and let D be the focus of marginal and F that of rays incident near the axis, such as ST. The greatest longitudinal aberration will therefore in this case be DF. Let GH, fig. 49, be now a concave lens, upon which are incident parallel rays SHRK. Let P be the virtual focus of marginal rays, such as SH, and N the focus of rays near the centre, such as RK, so that PN will be in this case the longitudinal aberration. The convex lens in fig. 48 is in the position which gives the least spherical aberration, and the concave lens in fig. 49 is in the position which gives the greatest aberration. Hence in order to make the aberrations equal, we must make the focal distance of the convex glass much shorter than that of the concave one, and if it is requisite to have the distance of the points F and N from the convex and concave lenses the same as it is shewn in the figures, the object must then be placed much nearer the convex lens. Hence the image of the near object S is placed at the same distance from the convex lens in fig. 48, or the virtual focus of the concave lens in fig. 49, where it is shewn as refracting parallel or infinitely distant rays.

Fig. 48.

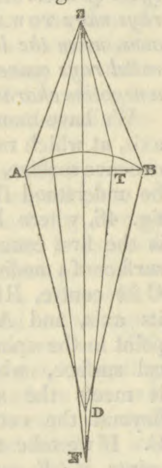


Fig. 49.

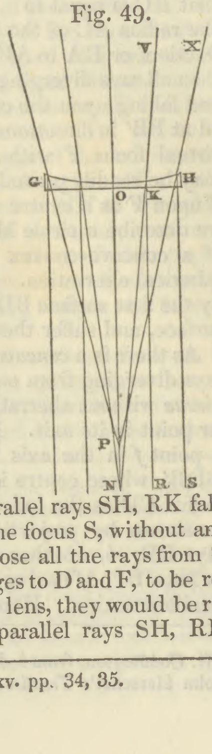
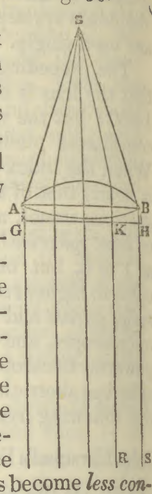


When the focal distance KN, therefore, for parallel rays is equal to the distance TF for rays diverging from S, and when the aberration DF and PN are equal, then if the two lenses are combined, as in fig. 50, parallel rays SH, RK falling upon them, will be refracted to the focus S, without any spherical aberration. For if we suppose all the rays from S, which the convex lens, fig. 48, converges to D and F, to be returned back from these points to the lens, they would be refracted accurately to S. But the parallel rays SH, RK, after refraction by the concave lens, fig. 49, in the directions HX, KV, are exactly in the same relative situation as the rays which we have supposed to be returned directly back from F and D are in at their incidence on the convex lens. Hence when these lenses are combined, as in fig. 50, parallel rays falling on the concave lens, and after refraction incident upon the convex lens, will be refracted accurately to S without any spherical aberration.[2]

Fig. 50.

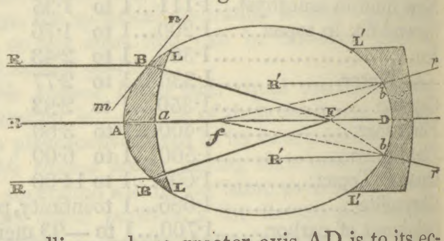


Spherical aberration.

The difficulty of getting rid of the aberration of spherical surfaces, induced opticians at a very early period to propose the construction of lenses that were not spherical, and that had such forms as to be entirely free of spherical aberration. As the marginal parts of spherical lenses refract the rays which fall upon them too much, the spherical aberration would obviously be removed or diminished, by giving the surface any curvature, in which the marginal parts become *less convex*. Now, this is the character of two well known curves, viz. the ellipse and the hyperbola, which, as Descartes discovered, may be employed in the formation of lenses in the following manner:—

Lenses spherical

Fig. 51.

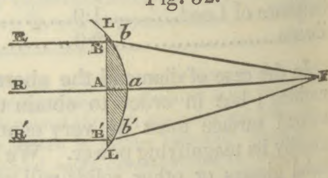


If a lens LL, fig. 51, has the form of a meniscus in which the convex surface LAL is part of a prolate spheroid formed by the revolution of an ellipse, whose greater axis AD is to its eccentricity or distance between its foci F, f as the index of refraction is to unity, and if the other surface LaL is concave, and part of a sphere whose centre is F, the remoter focus of the spheroid, then rays RB, RA, RB parallel to the axis RF of the spheroid or the ellipse will be refracted by the convex spheroidal surface alone to the remoter focus F, and as these rays fall perpendicularly upon the second surface LaL, they will suffer no change whatever by its action, and continue their progress to the focus F.

The same property belongs to a *concavo-convex* lens L′L′, whose anterior or concave surface is part of a prolate spheroid of the same dimensions as for the meniscus, and having its convex side of any radius. In this case, all rays R′b, R′b parallel to the axis and incident at b, b, will be made to diverge from the same virtual focus F, and will suffer no change of direction in passing out of the second or convex surface, as they all fall upon it perpendicularly.

These truths may be proved by the most elementary principles of the conic section, or by drawing a tangent *mn* to the elliptical surfaces at B, b, and determining the refracted rays by the method already described.

Fig. 52.



Upon the same principles a *plano-convex* lens may be constructed without spherical aberration, as shewn in fig. 52, provided its posterior surface LaL is part of a hyperboloid formed by the revolution of a hyperbola LaL, whose greater axis is to the distance between the foci as the index of refraction is to unity. Pa-

[2] See *Edinburgh Transactions*, vol. iii. p. 27.

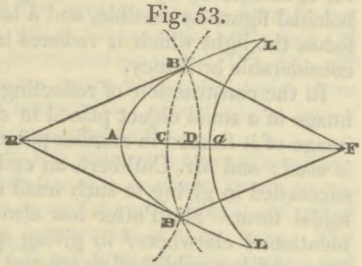
Spherical aberration.

rallel rays RB, RA, R′B′, will suffer no refraction at the plane surface BAB′, but at the points of the convex surface *b*, *b*′ will be refracted accurately to F, the further focus of the hyperboloid.

In like manner, a *plano-concave* lens having its concave surface part of a hyperboloid will diverge all rays so as to have their virtual focus in one of the foci of the hyperboloid.[1]

The following elegant method of determining the figure of a refracting surface which shall refract marginal and central rays to the same focus is due to Huygens. Let R be the focus of diverging rays, and F the focus to which it is required to refract them with accuracy. Take any point A as the vertex of the refracting surface required; the surface must be such that the incident and refracted rays RB, BF have such a ratio to each other, that the excess of RB above RA shall be to that of FA above FB, as the index of refraction is to unity. In order to find the curve BAB which possesses this property, take in the axis RF any point D, and let DA be divided at the point C in such a manner that AC is to AD as unity is to the index of refraction, and from R and F as centres, describe the arches of circles BDB′, BCB′, with the radii RD, FC, their points of intersection B, B′ will be in the required curve. In like manner, any other points in the curve may be found, and in order to convert it into a lens, we have only to describe a spherical surface L*a*L, round the focus F as a centre, so that the refracted rays BF, B′F may suffer no change by passing through it perpendicularly. The curve BAB gradually approaches to an ellipsoid as the radiant point R becomes more distant from the lens, and when it is infinitely distant, the curve is the section of an ellipsoid, whose further focus is in F.[2]

Fig. 53.



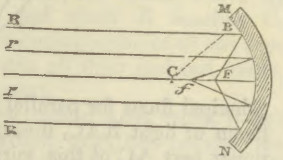
Various attempts have been made to execute lenses of other forms than spherical, but without decided success. Descartes has described machines for this purpose in the *tenth* chapter of his Dioptrics, but though he succeeded to a certain degree in his experiments, yet the art has never been acquired of producing figures sufficiently accurate for fine telescopes and microscopes.

Sect. II.—*Spherical Aberration of Mirrors.*

It has already been stated under *Catoptrics* in this article, that in all reflexions from spherical surfaces it is only for the ray near the axis that the rules for finding their foci are correct, those which fall farther and farther from the axis having their foci nearer the reflecting surface. Hence all the images which are formed by spherical surfaces are indistinct from spherical aberration, like those formed by lenses, with this difference, that the images are not confused with the different colours which always accompany the refraction of lenses.

If MN, fig. 54, is a concave mirror, by which parallel rays RR are reflected from its margin and *r*, *r*, from near its axis, it will be found from a simple projection of the reflected rays that R, R will invariably be reflected to a focus F nearer the mirror than the focus *f* of the central rays. The space F*f* is called the longitudinal or linear spherical aberration, and it will obviously become greater as the diameter of the mirror is increased, its focal length or its curvature remaining the same, and with its curvature when its diameter or aperture remains the same.

Fig. 54.

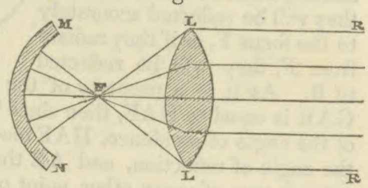


In all cases but *one*, the marginal rays have a shorter focus than the central ones, or what is the same, have their focus nearest the reflecting surface. This case takes place when the radiant point is situated between the surface and the principal focus on the *concave* side of the mirror, in which case the focus of marginal rays is *farther from* the mirror than that of central rays.

There are only *two* cases in which spherical reflecting surfaces have *no* spherical aberration, namely, when diverging rays radiate from the centre of a concave mirror or spherical surface, in which case they are reflected back without aberration to the point from which they came, without any aberration, and when they converge to the centre of a convex mirror or spherical surface, in which case they will be reflected back in lines diverging from the centre or virtual focus behind it without any aberration.

One of these cases, namely, the first, is not an ideal one, but is actually applicable to practical purposes. For example, if rays diverging from F the centre of curvature, (not the focus) of the reflecting mirror MN, fall upon the mirror, they will be reflected to F, and pass through F towards a lens LL, which will refract them into a parallel beam LLRR; if FL is the focal length of the lens, or into a converging beam, so as to illuminate strongly any near object, if FL is greater than the focal length of the lens. This contrivance has been proposed for light-house illumination, where, in addition to the beam FLL radiating directly from F the lens LL, receives also the other beam FMN, both of which it unites in one parallel beam LLRR. In the accurate illumination of objects for the microscope, this contrivance is also applicable; and hence for this purpose a *spherical* mirror is better than a mirror of any other form.

Fig. 55.



As we cannot in the case of reflectors diminish their spherical aberration as we did in lenses, by giving a different shape to the two surfaces, it becomes of great importance to form the reflecting surface in such a manner as to remove the spherical aberration altogether. It is evident from the inspection of fig. 54, where CB is a perpendicular to the mirror at B, RMC the angle of incidence, and CBF the angle of reflexion, that if the reflecting surface should be such that the line BF drawn to a fixed point, F should always form equal angles with a line CB perpendicular to the mirror at the point of incidence, the parallel rays would all converge to the point F. Now the *parabola* is a curve which possesses this property as shewn in fig. 56. Let AEB be a parabola which form a reflecting surface by its revolution round its axis RFE, and let R, R, R be parallel rays incident upon the paraboloidal surface at the points A, E, B. Then if F is the focus of the parabola, and GH a line touching the curve at A, it is a property of the parabola,[3] that the angle GAR is equal to HAF, but GAR is the complement of the angle of incidence, and therefore HAF will be the complement of the angle of reflexion, and

Fig. 56.

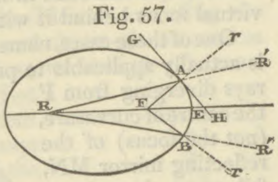
Spherical aberration.

consequently AF the reflected ray. As this is true for every ray parallel to the axis RFE, it follows that all parallel rays incident upon the surface of a paraboloidal mirror will be reflected accurately to the focus of the paraboloid.

It may be shewn, in like manner, that *convex paraboloidal reflectors* will reflect parallel rays, so as to make them diverge from the virtual focus of the paraboloid. If, in fig. 56, we continue the line RA to R, and also FA to rC, it follows, from the above reasoning, that R′AH is equal to raC, and that the reflected ray is Ar, diverging accurately from the focus F.

When we wish to reflect diverging rays to a focus, without aberration, we must have recourse to another solid of revolution, namely, a prolate spheroidal surface formed by the revolution of an ellipse round its greater axis. In this case, rays diverging from one of its foci will be reflected accurately, without aberration, to the focus F. This will be understood from fig. 57, where R, F are the foci of an ellipsoid, AEB a section of the ellipsoidal surface, and GH a line touching the ellipse at A; then if rays diverging from one of its foci R, fall upon the reflecting surface at A, E, and B, they will be reflected accurately to the focus F, or if they radiate from F, they will be reflected to R. As it is a property of the ellipse,[1] that the angle GAR is equal to HAF, then since GAR is the complement of the angle of incidence, HAF must be the complement of the angle of reflection, and AE the reflected ray. As the same is true of every other point of the ellipsoidal surface, it follows that all rays incident upon it from one focus, will be converged without aberration to the other focus.

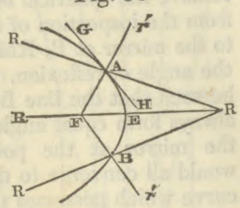
Fig. 57.



In like manner, it may be shewn, by producing RA to R′, and RB to R′, that rays falling upon a *convex ellipsoidal mirror*, and converging to one focus, will be reflected as if they diverged accurately from the other focus. That is, rays R′AR, R′BR, converging to R, will be reflected in diverging directions Ar, Br, as if they diverged from the focus F, or rays rA, rB converging to F, will be reflected in directions AR′, BR′, as if they diverged from R as their virtual focus.

If the concave surface of a mirror is a portion of a *hyperboloid*, a solid generated by the revolution of a hyperbola about its axis, rays converging to one focus will be reflected to the other focus. Let AEB be a section of the hyperboloid, and RAR, RBR′, rays converging to its focus; these rays will be reflected to its other focus F. Let GH be a tangent to the hyperbola at A, then by a well-known property of the hyperbola,[2] the angle GAR is equal to HAF; but the former being the complement to the angle of incidence, and the latter the complement to the angle of reflection, AF will be the reflected ray. For the same reason, if the rays *diverge* from the focus F, they will, after reflexion, diverge in the directions AR, BR, as if they came from the other focus R′.

Fig. 58.



In a similar manner, it may be shewn, that in a *convex hyperboloidal mirror* AEB, rays diverging from one focus R′, will be reflected in directions Ar, Br, as if they diverged from the other focus F.

The preceding truths are of great practical use in the construction of optical instruments. In all reflecting telescopes, where parallel rays are required to be reflected to a single focus, it is necessary that the figure of the reflecting surface should be that of a paraboloid; and as in the specula of such telescopes the portion of the paraboloid which is requisite, does not differ much from the same portion of a spherical surface that has the same focal length, artists have contrived particular methods by which the marginal parts of the spherical surface shall be worn down in the act of polishing, so as to convert the spherical into a paraboloidal surface.

In the reflectors of light-houses, where a large surface is required to be used, a copper plate thickly plated with silver is hammered by means of a gauge to as correct a paraboloidal figure as possible, and a lamp being placed in its focus, the light which it radiates is reflected in a beam of considerable brilliancy.

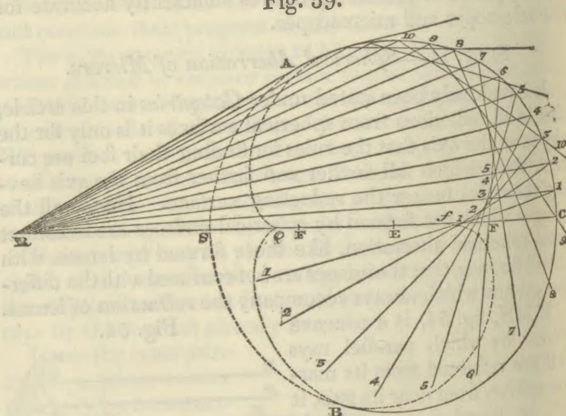
In the construction of reflecting microscopes, where the image of a small object placed in one spot has a magnified image of it formed in another point, an ellipsoidal speculum is used; and Mr. Cuthbert, an eminent London artist, has succeeded in giving to such small specula an accurate ellipsoidal form. Mr. Potter has also succeeded, as we have mentioned elsewhere,[3] in giving specula a true ellipsoidal form, and has published an account of the method by which he was able to effect this important object.[4]

SECT. III.—*On Caustic Curves formed by Spherical Reflecting and Refracting Surfaces.*

When two or more rays of light cross one another at any point, they illuminate any reflecting substance placed in that point with their united light. Hence it follows, that when spherical surfaces converge the rays which fall upon them to different foci, these different foci must form so many illuminated points, if they are received on smoke, on white paper, or on water with any reflecting particles suspended in it. The lines which pass through these luminous foci, or rather the lines formed by the union of a great number of them, are called *caustics*, or *caustic curves*. As these curves are in reality a visible representation of the phenomena of spherical aberration, they possess considerable interest, as experimental illustrations of that class of facts.

When diverging rays fall upon a spherical mirror, whose surface exceeds a hemisphere, the caustics formed by reflexion are exceedingly beautiful. Let ACB be the section of such a spherical surface, whose centre is C, and whose

Fig. 59.



principal focus for parallel and central rays is at f. Let a beam of light RAC, diverging from R, be incident on the upper part AC of this mirror, the beam consisting of the individual rays R1, R2, R3, &c., up to R10; and let the reflected rays 1, 1; 2, 2; 3, 3, &c., be found by making the angle of reflexion which they form with the perpendiculars

[1] See CONIC SECTIONS, vol. vii. p. 229, prop. v. cor. 4.
[2] Id. Id. p. 241, prop. v.
[3] Art. MICROSCOPE, vol. xv. p. 42.
[4] *Edin. Jour. of Science*, N. S., No. 12, p. 228.

drawn from 1, 2, 3, &c., to C, equal to the angles of incidence which they form with the same perpendiculars. We shall then have the directions, and also the foci and intersections of all the rays. The ray 10, 10 does not meet the axis RC at all, but falling on the mirror at the point 3, will there suffer a second reflexion. The ray 9, 9 has its focus exactly at C, the vertex of the mirror, where it will suffer a second reflexion, and so on with all the rest, up to 14, which is the last which will suffer a second reflexion. All the reflected rays, after 9, 9, cross the axis, or have their foci at points gradually approaching to f, which is the focus of the central ray R 1. As all the rays proceeding from R, but not drawn in the figure, which fall upon the other half CB of the mirror, at points corresponding to R 1, R 2, &c., will have their foci in the same points between C and f, there will be along that line a series of foci constituting a line of light becoming more intense towards f.

But the rays R 10, R 9, R 8, cross each other after reflexion, and before they reach the axis, as shewn in the figure, and hence there will be a beautiful curve of light Af, called a *caustic*, formed by the intersection of these rays. The other half of the mirror CB will form a similar caustic, and the projecting points f are called the *cusps* of these caustics, and Cf their tangent.

If a small pencil of light, consisting of two contiguous rays, moves from RA towards the position RB, being incident successively at 9, 8, 7, 6, &c., the conjugate focus of this pencil, or that formed by the intersection of the two rays of which it consists, will move along the caustic curve Af, while the points where it crosses the axis RC, or its focus formed by its union with a similar pencil similarly incident on the other half of the mirror, will advance from C to f.

If we now consider ACB as a *convex* spherical surface, and place the radiant point R as far to the right of the vertex C as it is to the left of it in the figure, and if we project the reflected rays, we shall find that when traced backwards, they will intersect the *axis* and each other, in the very same manner as they do in the figure, forming an *imaginary* or *virtual* caustic, in place of a *real* one, the two being in every respect the same.

If, while the radiant point R remains as in the figure, we suppose the convex surface ASB to receive the incident rays, it will then be found, by projecting the reflected rays, that they will form an imaginary caustic AφB, less than AfB, and joining it at the points A, B. This difference in size arises from the radiant point being in this case much nearer the convex surface than before.

Let us now suppose that the radiant point R recedes from the *concave* mirror ACB, the point f of the *cusps* will gradually approach to F, the tangent Cf diminishing at the same time; and when R is infinitely distant, or the rays parallel, the point f will coincide with F, the focus of parallel rays. The same will take place in the case of the *convex* mirror ACB; but in the case of the convex mirror ASB, the point φ of the cusps will approach to F′, and will coincide with it when R is infinitely distant.

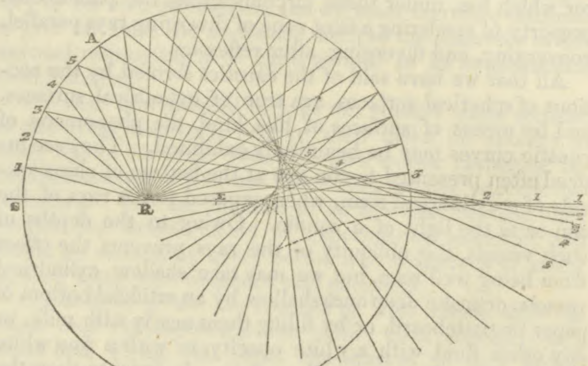
If, in the case of the *concave mirror* ACB, the radiant point R now approaches to the mirror, the cusps f will approach to the centre E of the mirror, the *caustic* curve Af becoming flatter and flatter, and when R reaches C, there will be no caustic at all, in consequence of all the rays being reflected back to the centre, all their *foci* and *intersections* having united in that point.

In the case of the *imaginary* caustic AφB, when R approaches to S, φ will also approach to S, the caustic approximating in form to the circular arch AS; and when R reaches S, φ will also reach S, the caustic disappearing when it has reached that limiting form.

All that we have said is obviously applicable only to one section of the spherical mirror; but as the same is true of every section whatever, the caustic will not be a curve, but a surface formed by the revolution of the curves AfB round its axis fC, all the reflected rays being tangents to this surface.

We shall now consider the change in the appearance of the caustic, when the radiant point comes within the sphere of which the reflecting surface is a part, and when the mirror becomes a concave polished sphere. The effect thus produced is shewn in fig. 60, RE being less than RS′. In this case a remarkable double caustic will be formed, com-

Fig. 60.



posed of a short one of the kind shewn in fig. 59, and another with two long branches, one of which is shewn at 1, 2, 3, 4, 5, the dotted line below the axis SE shewing the other halves of the caustic, the long branches converging behind the mirror. Had R been placed nearer S than E, the branches 1, 2, 3, &c., would have diverged behind the mirror, having their virtual foci within the mirror. When R is half-way between S and E, the curved branches become parallel lines. When R comes nearer E the branches 1, 2, 3, &c., shorten; the smaller caustics also shorten; they both approach to the centre E, the long branches moving quickest till at E, as we have already seen, all the rays from R are reflected back to the same point, and the caustics all disappear.

M. A. Delarive, in his ingenious dissertation on caustic curves,[1] has shewn that caustics generated by parallel rays are *epicycloids*, formed by one circle rolling upon a fixed circle concentric with that of the mirror, and having a radius equal to half of its own. Dr. Smith has shewn that when the radiant point is at S, the caustic is an epicycloid, whose generating circle is two-thirds of the radius of the mirror, and the fixed circle one-third of that radius.[2]

When the radiant point passes the centre E, the caustics shift their place to the opposite side of E, and present the same phenomena as before.

There is a curious property, however, involved in these phenomena, which we have represented in fig. 61, where the radiant point is supposed to be at F, a very little within the principal focus of a spherical mirror ACB. We have supposed the rays to diverge from a point *a little* within the principal focus, because it is only in this case that the rays F 1, F 1, at *a little* distance from the axis, may be reflected in directions 1, 1, 1, 1, exactly parallel. The rays F 2, F 2, falling at a greater distance from the axis, will be made to converge to a focus at f 2,

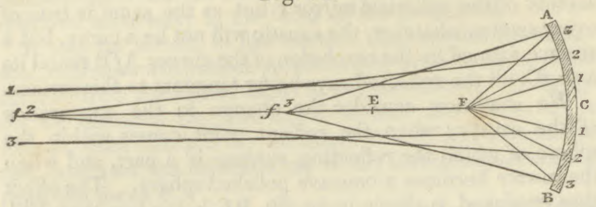
[1] *Dissertation sur la Partie de l'Optique qui traite des courbes dites Caustiques*, p. 84. Geneve, 1823. This interesting dissertation contains an account of the labours of preceding mathematicians, including Malus and Gergonne, and merits the attention of those who wish to prosecute the subject mathematically.

[2] *Complete System of Optics*, vol. i. p. 174.

Caustics.

and rays F 3, F 3, to a focus f 3, still nearer the mirror. If we now conceive rays flowing from F to fall on the mirror

Fig. 61.



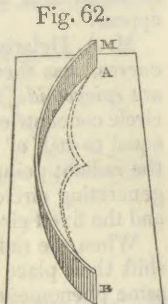
between the rays F 1, F 1, and the axis FC, these rays will diverge, because they radiate from a point a little within the principal focus, and hence we have one spherical mirror which has, under these circumstances, the paradoxical property of rendering a faint cone of diverging rays parallel, converging, and diverging, after reflexion.

Caustics from cylindrical surfaces.

All that we have said of the caustics formed by the sections of spherical surfaces, are true of cylindrical surfaces, and by means of surfaces of this kind, the phenomena of caustic curves may be beautifully exhibited. They are indeed often presented to the eye at the bottom of china vessels of a cylindrical form, when exposed to the rays of the sun or to the light of a candle. Owing to the depths of such vessels, the obliquity of the rays prevents the effect from being well seen, but we may take shallow cylindrical vessels, or make deep ones shallow by an artificial bottom of paper or pasteboard, or by filling them nearly with milk, or any other fluid with a white opacity, or with a fine white powder pressed into a smooth surface. In order to shew the caustics, when the radiant point is placed within the cylindrical surface, a piece of card should be made to float upon oil in the cylindrical vessel, and a very minute wick inserted in the card at the points of the axis where we wish the radiant point to be placed. This wick, when lighted, will be the radiant point R in fig. 60, and the caustics will be beautifully formed on the surface of the white card.

The following method, however, of exhibiting caustic curves, we have found very convenient and instructive, and it has the advantage of allowing the radiant point to come within the cylinder. A piece of steel-spring highly polished, such as a watch-spring, is bent into a concave form, like AB, fig. 62, and is placed vertically with its lower edge resting upon a piece of card or white paper. It is then exposed to the solar rays, or those of any artificial light, so that the plane of the card MN passes through the luminous body, and the caustic curves will be seen finely displayed, varying with the distance of the radiant point, and with the reflecting arch AB. By altering too the curvature of the arch and bending it into different known curves, either by applying a portion of its breadth to the required curves delineated upon a piece of wood, and either cut or burned sufficiently deep in the wood to allow the edge of the thin strip of metal to be inserted in it, a great variety of interesting phenomena may be observed. The brightest reflector is a thin strip of polished silver or plated copper. Gold and silver foil will also answer, or a strip of mica. A cylindrical section of a wide glass tube or a bottle, especially if a piece is cut out of them to allow the incident rays to pass to the reflecting surface in the plane nearly of the base of the cylinder, will produce the caustic curves in great perfection. The caustic curves produced by a highly gilt or polished metallic ring, such as the ring of a bell handle, are exceedingly beautiful, the phenomena of a convex and a concave surface being here united.

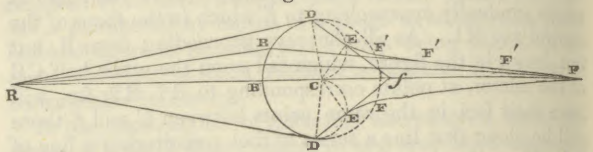
Fig. 62.



Caustics formed by Refracting Surfaces.

It is evident, from what has been said of caustics formed by reflexion or *Catacaustics*, that analogous curves must also be formed by spherical refracting surfaces, which has been called *Diacaustics*. In order to explain these curves, we shall take the case of diverging rays falling upon a spherical surface, as shewn in fig. 63. where DBDF is the spherical surface, C its centre, R the radiant point, RD, RD

Fig. 63.



two extreme rays touching the sphere, and refracted in the directions Df; Df, and RB, RB other rays nearer the axis, and refracted in the directions BF, BF. If we join CD, CD, and drawing the semicircles DEC, DEC make the lines DE, CE′ in the same proportion to CD as unity is to the index of refraction, the caustic will begin at EE′ and extending in the directions E, F′, F will approach to the axis RC till it meets it at the principal focus F.

The caustics formed by the two refractions of a sphere, or of a cylinder (in a plane perpendicular to its axis) are shewn in fig. 64, where ACB is the spherical section, E its

Fig. 64.

centre, R the radiant point, and RC the ray which touches the spherical surface. This ray will be refracted by the first surface in the direction 6,6, and by the second surface of the sphere at 6, the other rays R5, R4, &c. will be all refracted in the directions indicated by the numerals 5, 4, &c. and their various intersections will form the caustic 6, 4, 3, 2, 1, f, each ray crossing the next ray before it cuts the axis, f being the focus or the point where the rays nearest the axis cut it. The luminous figure bounded by the intersection of the successive rays, is composed of the two bright caustic curves. Within these caustics there is also much light arising from the intersections between the caustics and the axis; but as there are no intersections without the caustics they are bounded by absolute darkness.

When parallel rays fall upon the spherical section ACB, the caustic commences at the extremity of a diameter perpendicular to the axis of the section, because the extreme ray suffers refraction at that point, and will intersect the nearest a little within it, and they extend, as in fig. 64, to the principal focus of the sphere for rays near the axis. The real caustic will be the surface formed by the revolution of the curves round the axis Ef, the section of this curve will be a luminous point at f, but at the posterior surface it will be a luminous circle vividly depicted on the sphere. M. Delarive has pointed out a method of determining the index of refraction of solid spheres, or of hollow spheres containing different fluids, by measuring the diameter of this luminous circle, which is smaller in fluids of high than in those of low refractive power. The phenomena of caustics formed by refraction, may be distinctly exhibited by exposing to the rays of the sun, or a strong artificial light, a globe of glass filled with any fluid, or a solid transparent sphere, or the widest part of a round glass decanter. With all these bodies the whole of the luminous figure will be clearly seen. If we use a cylinder full of wa-

Chromatics.

ter, such as a tumbler or a cylindrical bottle, we shall see the caustic curves formed upon a white surface held parallel to the surface of the fluid, the light falling upon the cylindrical surface in the same plane.

PART II. ON THE REFRACTION OF COMPOUND LIGHT, OR THE DOCTRINE OF COLOURS AND THE PRISMATIC SPECTRUM.

In the preceding pages we have considered white light, whether emanating directly from the sun or from artificial flames, or consisting of the same rays reflected and modified by other bodies, *as a simple element* all the particles of which had the same index of refraction, or suffered the same change of direction when refracted by any transparent body. This, however, is not the nature of light. White light as emitted by the sun or other luminous bodies, is a very *compound element*, all the parts of which possess very different properties, and these properties are of a very remarkable and interesting kind. The power which causes the reflexion of light from polished metallic bodies is not capable of decomposing it, unless when it enters the substance of the metal; but the power which produces refraction is peculiarly influential in separating compound white light into its elements. The same decomposition may be effected by the *interference* of rays of light by *absorption*, and by another principle of analysis, which has been called *dissection.* The two first of these processes of analysis decompose compound light of different degrees of refrangibility; while the two last decompose compound light whose rays have the same refrangibility.

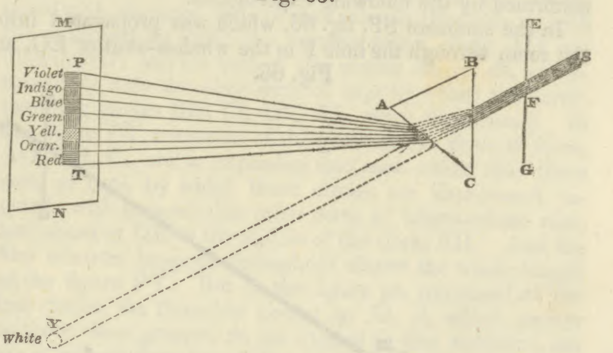
SECT. I.—*On the decomposition of light, and the different refrangibility of its rays.*

The constituent parts or colours which compose white light, are seven in number, *red, orange, yellow, green, blue, indigo,* and *violet.* These colours have been long observed and studied in the rainbow, and in the refractions produced by lenses and prisms, but till the time of Sir Isaac Newton, no satisfactory explanation had been given of their origin and properties. Descartes had found that colours similar to those of the rainbow were produced by prisms, and he endeavoured to explain them by saying, that the particles of the medium, or matter which transmits light, endeavour to revolve with so great force, that they cannot move in a straight line, whence comes refraction; and that those particles which endeavour to revolve more strongly produce a *red* colour, those that endeavour to move a little more strongly, produce *yellow*, and so on with the other colours. Now this explanation, as Mr. Whewell[1] has justly remarked, though it contains a gratuitous hypothesis respecting the cause of refraction, yet it proves that Descartes considered the different colours as produced by different degrees of refraction. In like manner Grimaldi, as the same author has observed, explains colours by saying, "that the colour is brighter where the light is dense; and the light is denser on the side from which the refraction turns the ray, because the *increments of refraction* are greater than the rays that are more inclined;"[2] that is, that the blue rays are more refracted than the red rays. We cannot agree, however, with Mr. Whewell in the opinion, that this explanation of Grimaldi's might give an explanation of most of the facts, but one much more erroneous than a development of Descartes's views would have been." It appears to us quite manifest, that both Descartes and Grimaldi had a vague sentiment that the different colours were produced by different degrees of refraction, and that Grimaldi's is the most distinctly expressed of the two; but we cannot for a moment agree with the author above quoted, "that Descartes was led very near the same point with Newton." The sentiments expressed by Descartes and Grimaldi, were mere notions of the moment, which authors often throw out without much thought, and which are employed in future times to pervert the history of science. If these two authors really thought that colours were produced by different degrees of refraction, why did they not, as they did other opinions, submit them to the test of an experiment, which required neither thought nor labour, and the means of making which were in their hands. Sir Isaac Newton was well acquainted with the writings of Descartes, and so much with Descartes's *notions* about colours, that the examination of them was the object which he had in view in purchasing his prisms. He never refers to them as anticipatory of his own discoveries, and we must therefore continue to give Sir Isaac the *undivided* merit of the discovery of the unequal refrangibility of light, as well as its experimental establishment.

We shall now proceed to give our readers some account of this great discovery, and we shall make no apology in doing this in Sir Isaac Newton's own words, abridging his descriptions where they are redundant, or have become unnecessary. We are induced to do this also, because they exhibit the finest model of experimental research, and should be studied by every person who is desirous of investigating truth with diligence and patience.

1. *The light of the sun consists of rays which differ in colour and refrangibility.*—In a very dark chamber, at a round hole F, fig. 65, about one-third of an inch broad,

Fig. 65.



made in the shutter of a window, I placed a glass prism ABC, whereby the beam of the sun's light, SF, which came in at that hole, might be refracted upwards, toward the opposite wall of the chamber, and there form a coloured image of the sun, represented at PT. The axis of the prism, was, in this and the following experiments, perpendicular to the incident rays. About this axis I turned the prism slowly, and saw the refracted or coloured image of the sun, first to descend, and then to ascend. Between the descent and ascent, when the image seemed stationary, I stopped the prism, and fixed it in that posture, for in that posture the refractions of the light at the two sides of the refracting angles, that is, at the entrance of the rays into the prism, and at their going out of it, are equal to one another.

Then I let the refracted light fall perpendicularly upon a sheet of white paper, MN, placed at the opposite wall of the chamber, and observed the figure and dimensions of the solar image, PT, formed on the paper by that light. This image was oblong, and not oval, but terminated by two rectilinear and parallel sides, and two semicircular ends. On its side it was bounded pretty distinctly; but on its ends very indistinctly, the light there vanishing by degrees. At

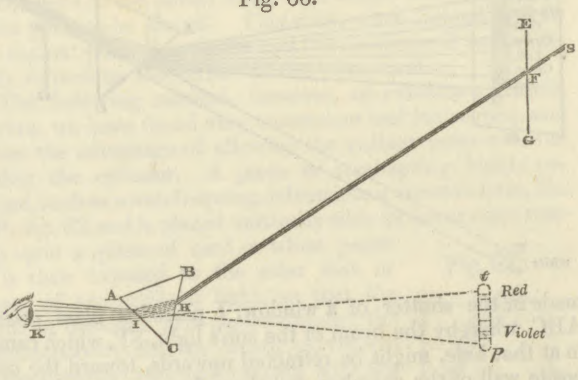
[1] *Hist. of Inductive Sciences*, vol. ii. p. 350. [2] Id. Id. p. 352.

the distance of $18\frac{1}{2}$ feet from the prism the breadth of the image was about $2\frac{1}{8}$ inches, but its length was about $10\frac{3}{4}$ inches, and the length of its rectilinear sides about 8 inches; and ACB, the refracting angle of the prism, by which so great a length was made, was 64 degrees. With a less angle the length of the image was less, the breadth remaining the same. It is also to be observed, that the rays went on in straight lines from the prism to the image, and therefore at their going out of the prism had all that inclination to one another from which the length of the image proceeded. This image PT was coloured, and the more eminent colours lay in this order from the bottom at T to the top at P; *red, orange, yellow, green, blue, indigo,* and *violet;* together with all their intermediate degrees in a continual succession perpetually varying."

Hence "the light of the sun consists of a mixture of several sorts of coloured rays, some of which at equal incidences are more refracted than others, and therefore are called *more refrangible.* The red at T, being nearest to the place Y, where the rays of the sun would go directly if the prism was taken away, is the least refracted of all the rays; and the *orange, yellow, green, blue, indigo,* and *violet,* are continually more and more refracted, as they are more and more diverted from the course of the direct light. For, when the prism is fixed in the posture above mentioned, so that the place of the image shall be the lowest possible, the figure of the image ought to be round, like the spot at Y, if all the rays that tended to it were equally refracted. Therefore, since it is found that this image is not round, but about five times longer than it is broad, it follows, that all the rays are not equally refracted. This conclusion is farther confirmed by the following experiments.

In the sunbeam SF, fig. 66, which was propagated into the room through the hole F in the window-shutter EG, at

Fig. 66.

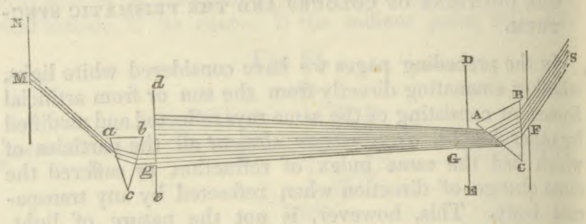


the distance of some feet from the hole, I held the prism ABC in such a posture, that its axis might be perpendicular to that beam: then I looked through the prism upon the hole F, and turning the prism to and fro about its axis to make the image *pt* of the hole ascend and descend, when between its two contrary motions it seemed stationary, I stopped the prism; in this situation of the prism, viewing through it the said hole F, I observed the length of its refracted image *pt* to be many times greater than its breadth; and that the *most refracted* part thereof appeared *violet* at *p;* the *least refracted* appeared *red* at *t;* and the *middle* parts *indigo, blue, green, yellow,* and *orange,* in order. The same thing happened when I removed the prism out of the sun's light, and looked through it upon the hole shining by the light of the clouds beyond it. And yet if the refractions of all the rays were equal according to one certain proportion of the sines of incidence and refraction, as is commonly supposed, the refracted image ought to have appeared round. So then by these two experiments, it appears that in equal incidences there is a considerable inequality of refractions."

Having discovered this fundamental property of light, he contrived the following experiment to prove it by ocular demonstration.

"In the middle of two thin boards DE, *de,* fig. 67, I made a round hole in each, at G and *g,* a third part of an inch in

Fig. 67.



diameter; and in the window-shutter a much larger hole being made at F, to let into my darkened chamber a large beam of the sun's light, I placed a prism, ABC, behind the shutter in that beam, to refract it towards the opposite wall; and close behind this prism I fixed one of the boards DE, in such a manner that the middle of the refracted light might pass through the hole made in it at G, and the rest be intercepted by the board. Then, at the distance of about twelve feet from the first board, I fixed the other board *de,* so that the middle of the refracted light, which came through the hole in the first board, and fell upon the opposite wall, might pass through the hole *g* in this other board *de,* and the rest being intercepted by the board, might paint upon it the coloured spectrum of the sun. And close behind this board I fixed another prism *abc,* to refract the light which came through the hole *g.* Then I returned speedily to the first prism ABC, and by turning it slowly to and fro about its axis, I caused the image which fell upon the second board *de* to move up and down upon that board, that all its parts might pass successively through the hole in that board, and fall upon the prism behind it. And in the mean time I noted the places *M, N,* on the opposite wall, to which that light after its refraction in the second prism did pass; and by the difference of the places at *M* and *N,* I found that the light, which, being most refracted in the first prism ABC, did go to the blue end of the image, was again more refracted by the second prism *abc,* than the light which went to the red end of that image. For when the lower part of the light which fell upon the second board *de,* was cast through the hole *g,* it went to a lower place M on the wall; and when the higher part of that light was cast through the same hole *g,* it went to a higher place N on the wall; and when any intermediate part of the light was cast through that hole, it went to some place in the wall between M and N. The unchanged position of the holes in the boards made the incidence of the rays upon the second prism to be the same in all cases. And yet in that common incidence some of the rays were more refracted and others less; and those were more refracted in this prism, which by a greater refraction in the first prism were more turned out of their way; and therefore, for their constancy of being more refracted, are deservedly called *more refrangible.*"

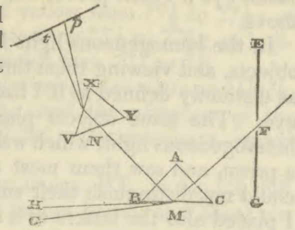
2. *The light of the sky, or the light of the sun reflected from the first surface of bodies, and also the white flames of all combustibles, whether direct or reflected, differ in colour and refrangibility, like the direct light of the sun.*

The truth stated in this proposition was established by Newton, by examining all those lights with a prism when they were faint, or transmitting them through the prism, as in section 1, when they were sufficiently intense.

3. *The light of the sun consists of rays differing in reflexibility; and those rays that are more refrangible than others are also more reflexible.*

A prism ABC, fig. 68, whose two angles at its base BC were equal to one another and half right ones, and the third at A a right one, I placed in a beam FM of the sun's light, let into a dark chamber through a hole F, one-third part of an inch broad; and turning the prism slowly about its axis until the light which went through one of its angles ACB, and was refracted by it to G and H, began to be reflected into the line MN by its base BC, at which till then it went out of the glass;

Fig. 68.



I observed that those rays as MH, which had suffered the greatest refraction, were sooner reflected than the rest. To make it evident that the rays which vanished at H were reflected into the beam MN, I made this beam pass through another prism VXY, and being refracted by it to fall afterwards upon a sheet of white paper *pt* placed at some distance behind it, and there by that refraction to paint the usual colours at *pt*. Then causing the first prism to be turned about its axis according to the order of the letters ABC, I observed that when those rays MH, which in this prism had suffered the greatest refraction, and appeared *blue* and *violet*, began to be totally reflected, the *blue* and *violet* light on the paper which was most refracted in the second prism received a sensible increase at *p*, above that of the red and yellow at *t*: and afterwards, when the rest of the light, which was *green*, *yellow*, and *red*, began to be totally reflected, and vanished at G, the light of those colours at *t*, on the paper *pt*, received as great an increase as the *violet* and *blue* had received before. Which puts it past dispute, that those rays became first of all totally reflected at the base BC, which before at equal incidences with the rest upon the base BC had suffered the greatest refraction. I do not here take any notice of any refractions made in the sides AC, AB, of the first prism, because the light enters almost perpendicularly at the first side, and goes out almost perpendicularly at the second; and therefore suffers none, or so little, that the angles of incidence at the base BC are not sensibly altered by it; especially if the angles of the prism at the base BC be each about 40°. For the rays FM begin to be totally reflected when the angle CMF is about 50°, and therefore they will then make a right angle of 90° with AC.

"It appears also from experiments, that the beam of light MN, reflected by the base of the prism, being augmented first by the more refrangible rays, and afterwards by the less refrangible, is composed of rays differently refrangible. The light whose rays are all alike refrangible, I call *simple, homogeneous* and *similar*; and that whose rays are some more refrangible than others, I call *compound, heterogeneous*, and *dissimilar*.

The colours of homogeneous lights I call *primary, homogeneous*, and *simple*; and those of heterogeneous lights, *heterogeneous* and *compound*. For these are always compounded of *homogeneous* lights.

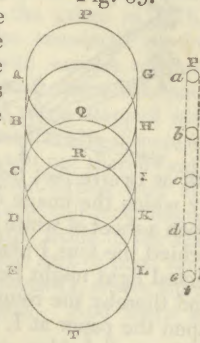
The *homogeneous* light and rays which appear *red*, or rather make objects appear so, I call *red-making*; those which make objects appear *yellow, green, blue*, and *violet*, I call *yellow-making, blue-making, violet-making*; and so of the rest. And if at any time I speak of light and rays as coloured or endowed with colours, I would be understood to speak not philosophically. For the rays, to speak properly, are not coloured, and in them there is nothing else than a certain power and disposition to produce a sensation of this or that colour."

4. *To separate from one another the heterogeneous rays of compound light.*

"That the rays which are equally refrangible fall upon a circle answering to the sun's apparent disk, will be proved by experiment by and by.

Let AG, fig. 69, represent the circle which all the most refrangible rays, propagated from the whole disk of the sun, will illuminate and paint upon the opposite wall if they were alone; EL the circle, which all the least refrangible rays would in like manner illuminate if they were alone; BH, CI, DK, the circles which so many intermediate rays would paint upon the wall, if they were singly propagated from the sun in successive order, the rest being intercepted; and conceive that there are other circles without number, which innumerable other intermediate sorts of rays would successively paint upon the wall, if the sun should successively emit every sort apart. And seeing the sun emits all these sorts at once, they must all together illuminate and paint innumerable equal circles; of all which being, according to their degrees of refrangibility, placed in order in a continual series, that oblong spectrum PT is composed, which was described in the first experiment.

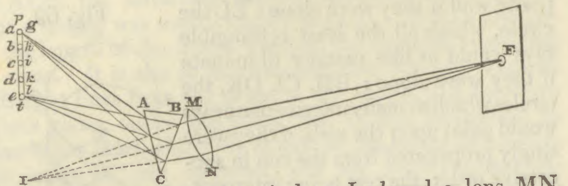
Fig. 69.



Now, if these circles, whilst their centres keep their distances and positions, could be made less in diameter, their interfering one with another, and consequently the mixture of the heterogeneous rays, would be proportionably diminished. Let the circles AG, BH, CI, &c. remain as before; and let *ag, bh, ci*, &c. be so many less circles lying in a like continual series, between two parallel right lines *ae*, and *gl*, with the same distance between their centres, and illuminated with the same sorts of rays: that is, the circle *ag* with the same sort by which the corresponding circle AG was illuminated; and the rest of the circles *bh, ci, dk, el*, respectively with the same sorts of rays by which the corresponding circles BH, CI, DK, EL, were illuminated. In the figure PT, composed of the great circles, three of those, AG, BH, CI, are so expanded into each other, that three sorts of rays, by which those circles are illuminated, together with innumerable other sorts of intermediate rays, are mixed at QR in the middle of the circle BH. And the like mixture happens throughout almost the whole length of the figure PT. But in the figure *pt*, composed of the less circles, the three less circles *ag, bh, ci*, which answer to those three greater, do not extend to one another; nor are there anywhere mingled so much as any two of the three sorts of rays by which those circles are illuminated, and which in the figure PT are all of them intermingled at QR. So then, if we would diminish the mixture of the rays, we are to diminish the diameters of the circles. Now these would be diminished if the sun's diameter, to which they answer, could be made less than it is, or (which comes to the same purpose) if without doors, at great distance from the prism towards the sun, some opaque body were placed with a round hole in the middle of it to intercept all the sun's light, except so much as coming from the middle of his body could pass through that hole to the prism. For so the circles AG, BH, and the rest, would not any longer answer to the whole disk of the sun, but only to that part of it which could be seen from the prism through that hole; that is, to the apparent magnitude of that hole viewed from the prism. But that these circles may answer more distinctly to that hole, a lens is to be placed by the prism to cast the image of the hole (that is, every one of the circles AG, BH, &c.) distinctly upon the paper at PT; after such a manner, as by a lens placed at a window the pictures of objects abroad are cast distinctly upon a paper within the room. If this be done, it will not be necessary to place that hole very far off, no, not beyond the window. And therefore, instead of that hole, I used the hole in the window-shutter as follows.

In the sun's light let into my darkened chamber through a small round hole, fig. 70, in my window-shutter, at about

Fig. 70.



ten or twelve feet from the window, I placed a lens MN, by which the image of the hole F might be distinctly cast upon a sheet of white paper placed at I. Then immediately behind the lens I placed a prism ABC, by which the trajected light might be refracted either upwards or sidewise, and thereby the round image which the lens alone did cast upon the paper at I, might be drawn out into a long one with parallel sides, as represented at *pt*. This oblong image I let fall upon another at about the same distance from the prism as the image at I, moving the paper either towards the prism or from it, until I found the just distance where the rectilinear sides of the images *pt* become most distinct. For in this case the circular images of the hole, which compose that image, after the manner that the circles *ag*, *bh*, *ci*, &c. do the figure *pt*, were terminated most distinctly, and therefore extended into one another the least that they could, and by consequence the mixture of the heterogeneous rays was now the least of all. The circles *ag*, *bh*, *ci*, &c. which compose the image *pt*, are each equal to the circle at I; and therefore, by diminishing the hole F, or by removing the lens farther from it, may be diminished at pleasure, whilst their centres keep the same distances from each other. Thus, by diminishing the breadth of the image *pt*, the circles of heterogeneal rays that compose it may be separated from each other as much as you please. Yet instead of the circular hole F, it is better to substitute an hole shaped like a parallelogram, with its length parallel to the length of the prism. For if this hole be an inch or two long, and but a tenth or twentieth part of an inch broad, or narrower, the light of the image *pt* will be as simple as before, or simpler; and the image being much broader, is therefore fitter to have experiments tried in its light than before."

5. *Homogeneal light is refracted regularly without any dilatation, splitting or shattering of the rays; and the confused vision of objects seen through refracting bodies by heterogeneous light, arises from the different refrangibility of several sorts of rays.*

In the middle of a black paper I made a round hole, about a fifth or a sixth part of an inch in diameter. Upon this part I caused the spectrum of homogeneous light, described in the former proposition, so to fall that some part of the light might pass through the hole in the paper. This transmitted part of the light I refracted with a prism placed behind the paper: and letting the refracted light fall perpendicularly upon a white paper, two or three feet distant from the prism, I found that the spectrum formed on the paper by this light was not oblong, as when it is made in the first experiment, by refracting the sun's compound light, but was, so far as I could judge by my eye, perfectly circular, the length being nowhere greater than the breadth; which shews that this light is refracted regularly without any dilatation of the rays, and is an ocular demonstration of the mathematical proposition mentioned above.

In the homogeneous light I placed a paper circle of a quarter of an inch in diameter; and in the sun's unrefracted, heterogeneous, white light, I placed another paper circle of the same bigness; and going from these papers to the distance of some feet, I viewed both circles through a prism. The circle illuminated by the sun's heterogeneous light appeared very oblong, as in the second experiment, the length being many times greater than the breadth. But the other circle, illuminated with homogeneous light, appeared circular, and distinctly defined, as when it is viewed by the naked eye; which proves the whole proposition mentioned above.

In the homogeneous light I placed flies and other minute objects, and viewing them through a prism I saw their parts as distinctly defined as if I had viewed them with the naked eye. The same objects placed in the sun's unrefracted heterogeneous light, which was white, I viewed also through a prism, and saw them most confusedly defined, so that I could not distinguish their smaller parts from one another. I placed also the letters of a small print one while in the homogeneous light, and then in the heterogeneous; and viewing them through a prism, they appeared in the latter case so confused and indistinct that I could not read them; but in the former, they appeared so distinct that I could read readily, and thought I saw them as distinct as when I viewed them with my naked eye: in both cases, I viewed the same object through the same prism, at the same distance from me, and in the same situation. There was no difference but in the lights by which the objects were illuminated, and which in one case was simple, in the other compound; and therefore the distinct vision in the former case, and confused in the latter, could arise from nothing else than from that difference in the lights. Which proves the whole proposition.

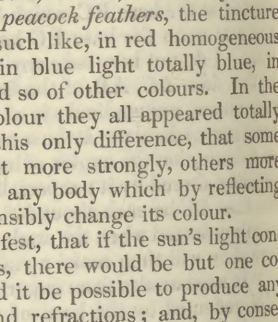
In these three experiments, it is farther very remarkable, that the colour of homogeneous light was never changed by the refraction. And as these colours were not changed by refraction, so neither were they by reflexions. For all white, grey, red, yellow, green, blue, violet bodies, as *paper*, *ashes*, *red lead*, *orpiment*, *indigo*, *bice*, *gold*, *silver*, *copper*, *grass*, *blue flowers*, *violets*, *bubbles of water tinged with various colours*, *peacock feathers*, the tincture of *lignum nephriticum*, and such like, in red homogeneous light appeared totally red, in blue light totally blue, in green light totally green, and so of other colours. In the homogeneous light of any colour they all appeared totally of that same colour; with this only difference, that some of them reflected that light more strongly, others more faintly. I never yet found any body which by reflecting homogeneous light could sensibly change its colour.

From all which it is manifest, that if the sun's light consisted of but one sort of rays, there would be but one colour in the world, nor would it be possible to produce any new colour by reflexions and refractions; and, by consequence, that the variety of colours depends upon the composition of light.

6. *Every homogeneous ray considered apart is refracted, according to one and the same rule; so that its sine of incidence is to its sine of refraction in a given ratio; that is, every differently coloured ray has a different ratio belonging to it.*

Sir Isaac Newton has proved this by experiment; and in other experiments he has determined by what numbers these given ratios are expressed. For instance, if an heterogeneous white ray of the sun emerges out of glass into air; or, which is the same thing, if rays of all colours be supposed to succeed one another in the same line AC, fig. 71. and AD their common sine of incidence in glass be divided into *fifty* equal parts, then EF and GH, the sines of refraction into air, of the least and most refrangible rays, will be 77 and 78 of such parts respectively.

Fig. 71.

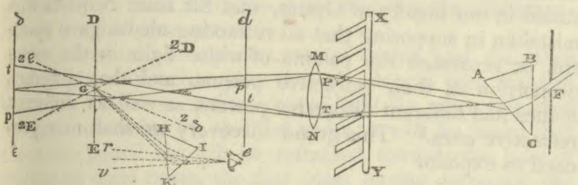


And since every colour has several degrees, the sines of refraction of all the degrees of red will have all intermediate degrees of magnitude from 77 to $77\frac{1}{8}$; of all the degrees of orange from $77\frac{1}{8}$ to $77\frac{1}{5}$; of yellow from $77\frac{1}{5}$ to $77\frac{1}{3}$; of green from $77\frac{1}{3}$ to $77\frac{1}{2}$; of blue from $77\frac{1}{2}$ to $77\frac{2}{3}$; of indigo from $77\frac{2}{3}$ to $77\frac{7}{9}$; and of violet from $77\frac{7}{9}$ to 78.

7. *Whiteness, and all grey colours between white and black, may be compounded of colours; and the whiteness of the sun's light is compounded of all the primary colours, mixed in a due proportion.*

"Let the spectrum or solar image PT, in fig. 72, fall upon the lens MN, above four inches broad, and about six

Fig. 72.



feet distant from the prism ABC, and so figured that it may cause the coloured light which divergeth from the prism to converge and meet again at its focus G, about six or eight feet distant from the lens, and there to fall perpendicularly upon a white paper DE. And if you move this paper to and fro, you will perceive that near the lens, as at *d e*, the whole solar image (suppose at *p t*) will appear upon it intensely coloured after the manner above explained, and that by receding from the lens those colours will perpetually come towards one another, and by mixing more and more, dilute one another continually, until at length the paper come to the focus G, where, by a perfect mixture, they will wholly vanish and be converted into whiteness, the whole light appearing now upon the paper like a little white circle. And afterwards by receding farther from the lens, the rays which before converged will now cross one another in the focus G, and diverge from thence, and thereby make the colours to appear again, but yet in a contrary order; suppose at δ ϵ, where the red *t* is now above which before was below, and the violet *p* is below which before was above.

Let us now stop the paper at the focus G, where the light appears totally white and circular, and let us consider its whiteness. I say, that this is composed of the converging colours. For if any of those colours be intercepted at the lens, the whiteness will cease and degenerate into that colour which arises from the composition of the other colours which are not intercepted. And then if the intercepted colours be let pass and fall upon that compound colour, they mix with it, and by their mixture restore the whiteness. So if the violet, blue, and green be intercepted, the remaining yellow, orange, and red, will compound upon the paper, an orange, and then if the intercepted colours be let pass they will fall upon this compounded orange, and together with it decompound a white. So also if the red and violet be intercepted, the remaining yellow, green, and blue, will compound a green upon the paper, and then the red and violet being let pass, will fall upon this green, and together with it decompound a white. And that in this composition of white the several rays do not suffer any change in their colorific qualities by acting upon one another, but are only mixed, and by a mixture of their colours produce *white*, may farther appear by these arguments.

If the paper be placed beyond the focus G, suppose at δ, and then the *red* colour at the lens be alternately intercepted, and let pass again, the *violet* colour on the paper will not suffer any change thereby, as it ought to do if the several sorts of rays acted upon one another in the focus G where they cross. Neither will the *red* upon the paper be changed by any alternate stopping, and letting pass the *violet* which crosseth it.

And if the paper be placed at the focus G, and the white round image at G be viewed through the prism at HIK, and by the refraction of that prism be translated to the place *r v*, and there appear tinged with various colours, namely, the *violet* at *v* and *red* at *r*, and others between, and then the *red* colour at the lens be often stopped and let pass by turns, the *red* at *r* will accordingly disappear and return as often, but the *violet* at *v* will not thereby suffer any change. And so by stopping and letting pass alternately the *blue* at the lens, the *blue* at *r* will accordingly disappear and return, without any change made in the *red* at *r*. The *red* therefore depends on one sort of rays, and the *blue* on another sort, which in the focus G, where they are commixed, do not act on one another. And there is the same reason of the other colours.

I considered farther, that when the *most* refrangible rays P*p*, and the *least* refrangible ones, T*t*, are by converging inclined to one another, the paper, if held very oblique to those rays in the focus G, might reflect one sort of them more copiously than the other sort, and by that means the reflected light would be tinged in that focus with the colour of the predominant rays, provided those rays severally retained their colours or colorific qualities in the composition of white made by them in that focus. But if they did not retain them in that white, but became all of them severally endued there with a disposition to strike the sense with the perception of white, then they could never lose their whiteness by such reflexions. I inclined therefore the paper to the rays very obliquely, as in the second experiment of this book, that the most refrangible rays might be more copiously reflected than the rest, and the whiteness at length changed successively into blue, indigo, and violet. Then I inclined it the contrary way, that the most refrangible rays might be more copious in the reflected light than the rest, and the whiteness turned successively to yellow, orange, and red.

Lastly, I made an instrument XY, in fashion of a comb, whose teeth were about an inch and an half broad, and the intervals of the teeth about two inches wide. Then by interposing successively the teeth of this instrument near the lens, I intercepted part of the colours by the interposed tooth, whilst the rest of them went on through the interval of the teeth to the paper DE, and there painted a round solar image. But the paper I had first placed so, that the image might appear white as often as the comb was taken away; and then the comb being, as was said, interposed, that whiteness by reason of the intercepted part of the colours at the lens did always change into the colour compounded of those colours which were not intercepted, and that colour was by the motion of the comb perpetually varied, so that in the passing of every tooth over the lens all these colours, red, yellow, green, blue, and purple, did always succeed one another. I caused therefore all the teeth to pass successively over the lens, and when the motion was slow, there appeared a perpetual succession of the colours upon the paper: But if I so much accelerated the motion, that the colours by reason of their quick succession could not be distinguished from one another, the appearance of the single colours ceased. There was no *red*, no *yellow*, no *green*, no *blue*, nor *purple*, to be seen any longer, but from a confusion of them all there arose one uniform *white* colour. Of the light which now by the mixture of all the colours appeared *white*, there was no part *really white*. One part was *red*, another *yellow*, a third *green*, a fourth *blue*, a fifth *purple*, and every part retains its proper colour till it strike the sensorium. If the impressions follow one another slowly, so that they may be severally perceived, there is made a distinct sensation of all the co-

Chromatics. lours, one after another, in a continual succession. But if the impressions follow one another so quickly that they cannot be severally perceived, there ariseth out of them all one common sensation, which is neither of this colour alone nor of that alone, but hath itself indifferently to them all, and this is a sensation of whiteness."

Such is the account which Newton himself has given of the great discovery of the different refrangibility of light.

In examining the prismatic spectrum it is difficult to discover the terminations or boundaries of the different colours. They pass into one another by insensible shades, and if any person were to lay down their apparent limits by the nicest observations, he would find, what has been very recently discovered, that these limits vary with the state of the atmosphere, and with the altitude of the sun. Sir Isaac Newton, however, did make the attempt, and the following are the results which he obtained, we believe with crown or plate glass. We have added the results obtained long afterwards by Dr. Wollaston[1] and Mr. Fraunhofer[2] with flint glass, which shews the difficulty of this class of observations.

	Newton in Crown Glass.	Fraunhofer in Flint Glass.	Wollaston in Flint Glass.
Red	45	56	57·6

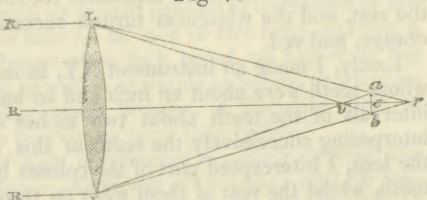
Blue	60	48	129·6
Indigo	48	47	
Violet	80	109	90
	360	360	360

Imperfection of refracting telescopes. The influence of these discoveries on the progress of optical science was very remarkable. They led Sir Isaac to discover that the cause of the imperfections of the refracting telescopes was the different refrangibility of the rays of light. If LL, for example, is a lens without spherical aberration, upon which parallel rays R, R, R of white light are incident, then it is obvious that the *violet*, or most refrangible rays will be most refracted in directions Lv, Lv, crossing the axis at *v*, and there giving a *violet* focus of light. In like manner the *red*, or the least refrangible rays, will be refracted in directions Lr, Lr, crossing the axis at *r*, and there giving a *red* focus of light. In like manner all the other rays will have foci of their own colour between *v* and *r*. If we draw the line *ab*, meeting the intersection of the extreme violet rays after their convergence with the extreme red rays before their convergence, it will cut the axis at a point *c*. The line *vr*, is called the *longitudinal aberration of refrangibility*, or the *longitudinal chromatic aberration*, and *ab* is called the *lateral aberration of refrangibility*, or the diameter of the *circle of diffusion*, all the coloured rays being diffused over the circle, of which *ab* is the diameter. The space *v a r b*, is called the sphere of diffusion; and the section of it shewn in the figure may be regarded as a parallelogram, on account of the smallness of the angles *r*Lv, *r*Lv, which are greatly magnified in the figure. Hence it may be easily shewn, that the longitudinal aberration *vr*, is to the lateral aberration *ab*, as the focal distance of the lens is to its radius or half its aperture.

Fig. 73.



In the circle of diffusion *ab*, the light becomes very faint towards *a* and *b*, and very intense in the centre *c*, so that there is formed at *c* a sort of general focus indistinct and coloured. Every part of an object, therefore, will have its image formed in the foci of such a lens similarly indistinct and similarly coloured, and hence we see the reason why refracting telescopes had such great imperfections, that it was necessary to make them of enormous lengths, in order to obtain a sufficient magnifying power.

From these causes, Sir Isaac Newton despaired of the improvement of refracting telescopes, and set himself at an early period of his life to execute reflecting telescopes. His successors, however, Mr. Hall and Mr. Dollond, studied the object of refraction as produced by prisms made of different substances, and found, as we have already fully stated in our history of Optics, that Sir Isaac Newton was mistaken in supposing that all refracting media gave spectra, or separated the colours of white light in the same proportion as their refractive powers, and that different bodies had different dispersive powers, as well as different refractive ones.[3] This grand discovery we shall now proceed to explain.

Sect. II.—*On the different Dispersive Powers of Bodies.*

The term *dispersion* has been employed to denote the separation of the different rays of white light into that divergent beam which constitutes the prismatic spectrum, the differently coloured rays having been dispersed or scattered by their different refrangibility. Sir Isaac Newton believed that all bodies whatever, whether *water*, or *crown*, or *plate*, or *flint glass*, dispersed light in an equal degree, provided the mean refraction, that is, the refraction of the mean or middle ray of the spectrum (the green ray, viz.), of these bodies was equal, or, in other words, that the dispersion, or the angle formed by the extreme red and the extreme violet ray was in different bodies proportional to the mean refraction.

As Sir Isaac Newton submitted to experiment a number of fluid substances, in the form of prisms, it is perhaps one of the most remarkable oversights in the history of science, that he did not think of comparing the length of the spectra which they formed; and it is equally strange that for more than a century he and all his successors should never have thought of forming the spectrum from any other luminous body less in diameter than the sun, or even from any luminous line of small breadth.[4] The consequence of these oversights was, that the most important discoveries relative to light, and to optical instruments, were reserved for another age.

In our *History of Optics*, and in the article Achromatic Glasses, we have given a detailed history of the successive labours of Hall, Dollond, Euler, and others, by which the achromatic telescope was invented and perfected.

If we perform the experiment shewn in fig. 65, with two prisms, the one of *flint*, and the other of *crown* glass, and measure in each the length of the spectrum PT, or rather the angles which the violet and the red rays PA, TA, make with each other, and the angle which the mean *green* ray forms with the direction of the coloured rays SY, this last angle will be the mean refraction of the prism, and the first the angular dispersion. We shall then find, that while in crown glass the quotient obtained by dividing the greater by the lesser angle, or the part of the mean refraction to which the dispersion is equal, will be seventeen hundredths, ($\frac{17}{100}$), while in flint glass it will be thirty hundredths, ($\frac{30}{100}$), this number varying with the nature of the glass.

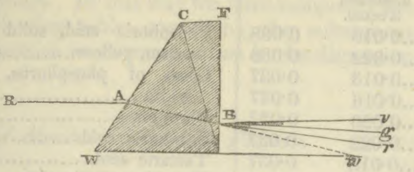
This result may be exhibited to the eye, by placing behind a prism of crown glass C, another of flint glass F, of such an angle as not to produce any deviation by refraction, the

[1] See page 414, col. 2.
[2] These results are taken from his coloured figure of the spectrum.
[3] See our Article Achromatic Glasses, vol. i. p. 97.
[4] See page 406, col. 1.

Chromatics

angle of deviation of the green ray produced by the *crown glass* prism C, being compensated by an equal and opposite deviation produced by the *flint glass* prism F; that is, the *green* ray B*g* will emerge parallel to the incident ray RA. When this has been effected it will be seen that there is still a spectrum *rv*, which will colour the edges of any object which is viewed through the prism, and in which will have the same position as if they had been produced by a small flint glass prism placed in the same manner as the flint glass prism F.

Fig. 74.

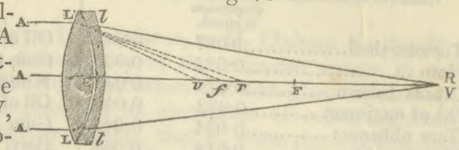


If we now take two prisms, one of *crown*, and the other of *flint* glass, of such angles, that all objects seen through them are colourless, or that a ray of light B*g*, when refracted by them, as in fig. 74, shall be white, it will be found that the white pencil B*w* will be refracted towards the base of the crown glass prism, the flint glass having corrected the colour produced by the crown glass one, but still left a considerable balance of refraction produced by the latter.

Hence it is manifest that the *colours* produced by a convex lens of *crown* glass, as shewn in fig. 73, may be corrected by a concave lens of *flint* glass, while the rays produced by the unbalanced refraction of the convex glass are still converged to a focus. Such a combination of lenses is called an *achromatic object-glass*, and a telescope in which such an object-glass is used is called an *achromatic telescope.*

Nothing is easier than to determine by experiment, when we have obtained good glass for the construction of these lenses, the proper radii to which they should be ground, in order to correct the aberration of colour; but it may be readily shewn, and the reader may easily prove it by the methods already described, that *the aberration of colour produced by a convex lens of crown glass will be corrected by a concave lens of flint glass, provided the focal lengths of the two lenses are proportional to their dispersive power.* Thus, in fig. 75, if LL is a convex lens of crown glass, whose focus for green rays is at *f*, and for violet and red rays at *v* and *r*, and if F is the virtual focus of a concave lens *ll* of flint glass, for the mean green ray, then parallel rays AAA will be refracted to a single focus at RV, where the violet and red rays will be united, provided the focal length of *ll*, viz., EF, is to E*f*, the focal length of LL as 0·068, the dispersive power of *flint* glass, is to 0·033, the dispersive power of *crown* glass.

Fig. 75.



Dispersive powers of bodies.

The dispersive powers of various glasses, and of some fluids, had been measured with considerable care, in reference to the improvement of the telescope, but no attempt was made to investigate it as a branch of physics, exhibiting new and interesting properties of transparent bodies. Dr. Wollaston set the example of beginning this inquiry, and he determined in a very general manner the dispersive qualities of thirty-three substances, which he arranged in the order of their dispersive powers, without giving any numerical estimate of their value. In this state of the subject, Sir David Brewster, by a new method of measuring dispersive powers, which presented considerable facility of observation, made a very extensive series of experiments on the subject, which, in a physical point of view, presented several curious results. In laying the following table of his observations before our readers, we must warn them that they were made, often with the most imperfect specimens of the minerals and fluid substances, from the difficulty of getting any other, and that they were intended only to indicate the general properties of bodies in dispersing light. The want of fixed points in the spectrum, in reference to which the measures could be taken, rendered it necessary to use the extreme points, which varied with the intensity of the light employed, and with the absorbing action of the bodies themselves, when they happened to be coloured or imperfectly transparent. The discovery of the fixed lines, and their use in measuring dispersive powers, introduced by Fraunhofer, has given a new impetus to this subject, and when it is practicable to obtain good prisms of the substance under examination, no other method will or should be adopted.

Table of the Dispersive Powers of various Solid and Fluid Bodies.

Names of substances.	Part of the whole refraction to which the dispersion is equal.	Dispersive power.
Chromate of lead (greatest refraction), estimated at	0·770	0·400
Chromate of lead (greatest refraction), must exceed	0·570	0·296
Realgar, a different kind, melted	0·394	0·267
Chromate of lead (least refraction)	0·388	0·262
Realgar, melted	0·374	0·255
Oil of cassia	0·089	0·139
Sulphur, after fusion	0·149	0·130
Phosphorus	0·156	0·128
Sulphuret of carbon	0·077	0·115
Balsam of Tolu	0·065	0·103
Balsam of Peru	0·058	0·093
Carbonate of lead (greatest refraction)	+0·091	+0·091
Barbadoes aloes	0·058	0·085
Essential oil of bitter almonds	0·048	0·079
Oil of anise seeds	0·044	0·077
Acetate of lead, melted	0·040	0·069
Balsam of styrax	0·039	0·067

Names of the Substances.	Part of the whole refraction to which the dispersion is equal.	Dispersive power.
Guiacum	0·041	0·066
Carbonate of lead (least refraction)	0·056	0·066
Oil of cummin	0·033	0·065
Essential oil of tobacco	0·035	0·064
Gum ammoniac	0·037	0·063
Oil of Barbadoes tar	0·032	0·062
Oil of cloves	0·033	0·062
Green coloured glass	0·037	0·061
Sulphate of lead	0·056	0·060
Deep red glass	0·044	0·060

The following measures of the dispersive powers of several varieties of glass were taken by Sir John Herschel, by a method which gave him nearly the extreme rays of the spectrum, namely, by viewing the spectrum through a dark blue glass, which stops the *green*, *yellow*, and most refrangible *red* rays, and therefore allows the extreme rays of the spectrum to be seen,—rays which the eye does not recognise in any of the ordinary lights which are used in optical instruments. If we condense the sun's light, as we have done, in order to render visible rays at the extremities of the spectrum, that have not been recognised, we should obtain dispersive powers still higher than those given by Sir John Herschel. By determining, however, the extremities of the spectrum seen by the ordinary light of the sky, it would be easy to accommodate all measures of dispersive power taken in such a light to those taken in the light used by Sir John Herschel, or in the more condensed and consequently elongated spectrum to which we have referred. In order that the measures in the following tables may be correct, it is necessary that they should all have been taken when the sun had the same altitude, because it is quite certain that the violet part of the spectrum diminishes in length very rapidly as the sun approaches the horizon, and some change also takes place at the red extremity.

Dispersive Powers of different kinds of Glass.

Plate glass,	0·02616	0·05090

Sir John Herschel justly remarks, that it ought not to excite surprise that the dispersions deduced by this method should considerably exceed all former estimates.[3]

Explanation of the Table.

In the preceding table of dispersive powers we have given two columns of numerical results, the first column containing the part of the whole refraction, or angle of deviation to which the angle of dispersion is equal, and the other the dispersive power itself. The first column is obviously not a measure of the dispersive power, because if the dispersion in that column is $\frac{1}{20}$th part of a low refraction in one body, and the 20th part of a high refraction in another body of great refractive power, the dispersive power of the latter must be smaller than that of the former, in the inverse ratio of the index of refraction of the two bodies minus unity. Hence the numbers in the second column, the dispersive powers, are obtained by dividing the first column by the index of refraction minus one.

Absolute dispersive power.

If we wish to have the intrinsic or *absolute* dispersive powers of bodies, in reference to the action of their ultimate molecules on the theory of emission, and on the supposition, as Sir John Herschel has remarked, in reference to absolute

[1] The dispersive power of the other image is considerably greater than this. See *Edin. Trans.* vol. vii. p. 289.
[2] The least refractive index of this salt, which is not inserted in our table, p. 384, is 1·379.
[3] *Edin. Trans.* vol. ix. p. 458.

Chromatics

s refractive powers, *of the ultimate atoms of all bodies being equally heavy,* we must divide the numbers in the second column of the preceding table by the specific gravities or densities of the bodies. In this way we have computed the results in the following table, containing the substances principally that exercise an extreme action in the dispersion of light.

Table of Absolute Dispersive Powers.

	Specific gravities used.	Absolute dispersive power.
Sulphate of barytes,	4·48	0·00602
——— strontites,	3·95	0·00607
Carbonate of barytes,	3·70	0·0063
Sapphire,	3·50	0·0066
Chryso-beryl,	3·93	0·00675
Topaz,	3·50	0·00685
Fluor spar,	3·17	0·0069
Cryolite,	2·95	0·0074
Diamond,	3·50	0·0109
Plate glass,	2·76	0·0112
Rock salt,	2·143	0·0250
Water,	1·00	0·035
Amber,	1·04	0·0400
Oil of olives,	0·913	0·0415
Oil of turpentine,	0·87	0·0483
Sulphur, fused,	2·00	0·065
Realgar,	3·50	0·0728
Phosphorus,	1·75	0·0731
Oil of anise seeds,	0·987	0·078
Bi-sulphuret of carbon,	1·27	0·081
Oil of cassia,	1.044	0·131

These results present us with several views of considerble interest. The salts of barytes have, in reference to heir density, the least dispersive power of all bodies, and he next in order are the gems, including even diamond, which occupies so different a place in our table of absolute efractive powers. The inflammable bodies, with the exeption of diamond, stand at the head of the table, *oil of assia* having by far the greater absolute dispersive power f any body yet examined. That this is owing to the hyrogen which it contains is very probable, and has almost een proved by an experiment by Sir John Herschel, who eprived a portion of this oil of most of its hydrogen by aking a stream of chlorine pass through it till it refused act any farther. By this means he converted the oil nto a viscous mass, the dispersive power of which was diinished one-half, while its refractive power had hardly uffered any change. This result leads us to conclude that *ydrogen* has the greatest intrinsic dispersive power of all odies. *Fluorine* seems to be the element which has nearly e lowest refractive power.

One of the most interesting results exhibited in the geeral Table of dispersive powers, relates to the dispersive owers of doubly refracting substances. Dr. Wollaston d measured the dispersive power of the ordinary ray in lcareous spar, so far at least as to ascertain that it stood ove water, and plate and crown-glass. Sir David Brewshad been led to measure the dispersion of the extraordiry ray, and found it to be much lower than that of water. was hence induced to examine the dispersive powers of er doubly refracting crystals, and was thus led to the ret which we have stated.[1] Similar results have been re recently obtained by M. Rudberg and Mr. Cooper, hout knowing that the subject had been previously invested.

SECT. III.—*On the Irrationality of the Coloured Spaces in the Spectrum, and the existence of a secondary Spectrum.*

We are indebted, we believe, to M. Clairaut for the discovery of the irrationality of the coloured spaces in the spectrum. He found that when the flint-glass of an achromatic object glass had its aberration of colour as completely corrected as possible, that is, when the extreme red and violet rays were accurately united in the same focus, still there remained a portion of incorrected colour, which was of a purple or claret colour on one side of the focus, and of a green colour on the other. If prisms had been used in place of lenses, and the sun's light transmitted through them in the usual manner, there would have been a small recidual spectrum, or *secondary spectrum* as it has been called, consisting of purple and green light. The Abbé Boscovich afterwards observed the same fact, but considered it so extraordinary that he suspected some latent cause of error, and submitted his experiments to the most rigid scrutiny. He at last admitted the irrationality of the coloured spaces in the spectrum as a demonstrated truth, and has shewn how three of the colours of the spectrum may be corrected or united in the same focus in achromatic telescopes. The late Professor Robison obtained similar results, and gave the name of *outstanding* colours to those which were not united, and form the secondary spectrum.

Secondary spectrum.
Clairaut.
Boscovich.
Robison.

This subject was more fully investigated by Dr. Blair, in his interesting paper on the unequal refrangibility of light,[2] and he has shewn that the proportions of the coloured spaces vary with the substance of the opposing prisms, so that a complete correction of colour cannot possibly be effected by two media of different dispersive powers. Hence Dr. Blair was led to examine the nature of the dispersive action of different media, and by the most ingenious devices succeeded in producing fluid object-glasses in which the *aberration of colour was completely corrected.* The telescopes which he made on this principle were so extraordinary, that Professor Robison assures us that one of them, FIFTEEN inches in focal length, *equalled in all respects, if it did not surpass, the best of Dollond's* FORTY-TWO inches long.

Blair.

Under these circumstances, the scientific world was surprised at the following statement published by Dr. Wollaston in the *Phil. Trans.* for 1803. "Since the proportions of these colours *have been* supposed by Dr. Blair to vary according to the medium by which they are produced, I have compared with this appearance, the coloured images caused by prismatic vessels containing substances supposed by him to differ most in this respect, such as strong but colourless nitric acid, rectified oil of turpentine, very pale oil of sassafras, Canada balsam, also nearly colourless. With each of these, I have found the same arrangement of these four colours, and in similar positions of the prisms, as nearly as I could judge, the same proportions of them." Dr. Blair was surprised that Dr. Wollaston should have used such a coarse method of determining a point that required delicate observations, especially with the substances above mentioned; and he remarked to the writer of this article, that if Dr. Wollaston would only make use of lenses, he would see his mistake after a single observation.

Wollaston.

There is no doubt, however, that the secondary spectrum can be made very visible by prisms, and if we use a prism of oil of cassia to correct the colour produced by another of sulphuric acid, we shall have a striking ocular proof of the existence of a large secondary spectrum.

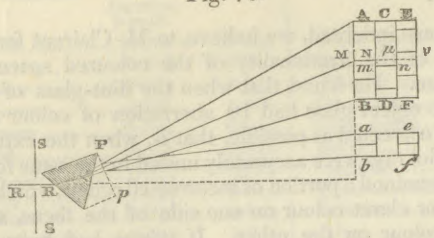
The phenomena of a secondary spectrum will be understood from fig. 76, where RR is a ray passing through an aperture in the window-shutter SS, and refracted by a prism P in the direction PM, so as to form the spectrum AB on the

[1] See *Phil. Trans.* 1813, p. 107, where this result was first published.

[2] *Edin. Trans.* vol. iii. p. 3.

wall, PA being the extreme violet ray, PM the mean ray, and PB the extreme red. The spectrum will consist of four

Fig. 76.



palpable colours, *red, green, blue, and violet*, and if the prism is one of *crown-glass*, the mean ray PMN which bisects the spectrum will be at the boundary of the blue and green spaces. If we were to take a prism of flint-glass with a much less refracting angle, and form a spectrum CD of the same length as AB, and at the same distance from the prism, the line *mn* which marks the boundary of the blue and green spaces will no longer be the mean ray of the spectrum, but will be decidedly nearer the *red* extremity D. The least refrangible half of the spectrum has therefore been more contracted, and the most refrangible half more expanded than in the crown-glass spectrum. If we now take a prism of sulphate of barytes or fluor spar, capable of forming a third spectrum EF of the same length as the other two, the boundary of the blue and green spaces will now be at $\mu\nu$ nearer the violet than the red extremity of the spectrum, and the least refrangible half of this spectrum will be more *expanded*, and the most refrangible half more *contracted*, than in the crown-glass spectrum.

"If a spectrum," says Sir David Brewster, [1] "formed by flint-glass, had its coloured spaces exactly of the same dimensions with those of an equal spectrum formed by crown-glass, any object such as a window-bar lying parallel to the common section of the refracting planes of the two prisms should appear perfectly colourless when seen through the combined prisms. But if the coloured spaces in the two spectra are not proportional, as shewn in fig. 76, but are *irrational*, then the window-bar cannot be wholly free from colour, for though the extreme red and violet rays of both the spectra are united, yet the intermediate colours are not rendered coincident. In the spectrum AB, formed by the crown-glass, the first green ray MN, which is here the mean ray, is obviously more refracted than the first green ray *mn*, in the spectrum CD formed by the flint-glass, and therefore the flint-glass will not be able to refract the green ray, so as to unite it with the red and violet. Hence the green ray will, as it were, be left behind, while the red and violet rays are rendered coincident. Thus, in fig. 76, if a prism *p* of flint glass is placed behind a crown-glass prism P, so as exactly to correct its dispersion, the spectrum AB will be reduced to a secondary spectrum *ab*, the upper half of which is *green*, which is left behind, and the lower half is of a *claret* colour, formed by the union of the red and violet rays. If the bar of a window had been examined through the combined prisms P, *p*, the upper side of it would have been tinged with green, and the lower side of it with a claret-coloured fringe.

By comparing, in a similar manner, the spectrum EF, formed by fluor spar, with the spectrum AB, formed by crown glass, it will be found, that the fluor spar having a greater action than the crown glass upon the green ray, will carry it beyond the place of the united red and violet, and will form a secondary spectrum *ef*, the lower half of which is *green*, and the upper half of a *claret* colour, arising from the union of the red and violet light. If the bar of a window were viewed through the combined prisms of crown-glass and rock crystal, it would be tinged with green on its lower side, and with a claret-coloured fringe on its upper side.

When a horizontal window-bar, therefore, is seen through any two prisms which correct each other's dispersion, without uniting all the colours, the green fringe will always be on the same side of the bar with the vertex of the prism which has the least action upon the green light, or which *contracts* the red and green rays, and *expands* the blue and violet ones; that is, if the vertex of the flint glass prism is pointing downwards, the uncorrected green fringe will be on the lower side of the bar. By observing, therefore, the position of the green fringe, we can immediately ascertain which of the two prisms has the greatest action upon the green light.

These theoretical deductions from the assumed inequality of the coloured spaces are completely established by observation.

The following Table contains the result of a numerous series of observations made by Sir David Brewster on the secondary spectra of different bodies, the substances being arranged inversely according to their action upon green light. The bodies at the top of the Table form spectra, in which the red and green spaces are most contracted, and the blue and violet ones most expanded. The relative position of some of the substances, particularly the essential oils, is quite empirical; but by a reference to the original experiments, it will be seen whether or not the relative action of any two bodies has been determined.

Table of Transparent Bodies, arranged inversely according to their Action upon Green Light.

1 OIL OF CASSIA.
Sulphur.
Sulphuret of Carbon.
Balsam of Tolu.
5 Carbonate of lead.
Essential oil of bitter almonds.
Oil of anise seeds.
Oil of cummin.
Oil of sassafras.
10 Oil of amber.
Acetate of lead melted.
Opal-coloured glass.
Orange-coloured glass.
Red-coloured glass.
15 Oil of sweet fennel seeds.
Oil of cloves.
Muriate of antimony.
Oil of lavender.
Canada balsam.
20 Oil of Turpentine.
Oil of sage.
Oil of pennyroyal.
Oil of poppy.
Oil of hyssop.
25 Oil of spearmint.
Amber.
Oil of lemon.
Oil of caraway-seeds
Oil of nutmegs.
30 Oil of thyme.
Oil of peppermint.
Oil of bergamot.
Oil of marjoram.
Oil of wormwood.
35 Oil of dill seeds.
Oil of chamomyle.
Castor-oil.
Gum copal.
Rosin.
40 Diamond.
Nitrate of potash.
Oil of beech-nut.
Oil of rue.
Oil of Savine.
45 Nut-oil.
Balsam of capivi.
Oil of fenugreek.
Oil of rosemary.
Oil of rhodium.
50 FLINT GLASS.
Zircon.
Oil of olives.
Oil of rape seed.
Oil of spermaceti.
55 Oil of Juniper.
Oil of ambergris.
Calcareous spar.
Rock-salt.
Gum juniper.
60 Tartrate of potash and soda.
Oil of almonds.
CROWN GLASS.
Gum-Arabic.
Alcohol.
65 Ether.
Borax, glass of.
Borax.
Tourmaline.
Leucite.
70 Selenite.
Beryl.
Topaz blue.
Fluor spar.
Citric Acid.
75 Malic Acid.
Ascetic acid.
Nitrous acid.
Muriatic acid.
Prussic acid.
80 Nitric acid.
Rock crystal.
White of an egg.
Ice.
WATER.
85 Super-sulphuretted hydrogen.
Phosphorous acid.
Sulphurous acid.
Phosphoric acid.
89 SULPHURIC ACID.

[1] *Treatise on New Philosophical Instruments*, 1813, p. 316.

Chromatics

Dr. Blair's aplanatic telescopes.

Finding it impossible to obtain any highly dispersing medium which should refract the rays of the spectrum in the same manner as crown glass, Dr. Blair thought of employing this very imperfection in obtaining a perfect correction of colour. As the green rays removed the outstanding ones, or were not united in the same focus with the red and violet, he considered that if an achromatic *concave* lens should refract the outstanding green more strongly than the united red and violet, while an achromatic *convex* lens should also refract the outstanding green more strongly than the united red and violet, then two such achromatic lenses combined might unite the outstanding green with the red and violet, and thus effect a perfect union of all the colours. Hence he took the combination shewn in fig. 77, for a concave lens, composed of a concave lens *ab*, of crown glass, and a convex lens *cd* of a fluid which had its dispersive power of such a character as to unite the *red* and *violet* rays as stated in the figures, and leave the green outstanding and *most refracted.* He then made an achromatic *convex* lens, fig. 78, composed of a convex lens *hg* of an essential oil, the same as that in *cbd*, which disperses the rays in a lesser degree, and of a concave lens *fehg* of an essential oil which disperses the rays in a much greater degree. This compound lens has its convexity such as to unite at a convenient distance, rays which diverge from the violet focus of the compound concave lens shewn in fig. 77, and therefore its focal length must be much shorter than the other, like the flint lens in a common achromatic. But though the focal lengths of the two compound lenses are thus different, yet, the distance or deviation of the outstanding green, from the united red and violet, is equal in both.

Fig. 77.

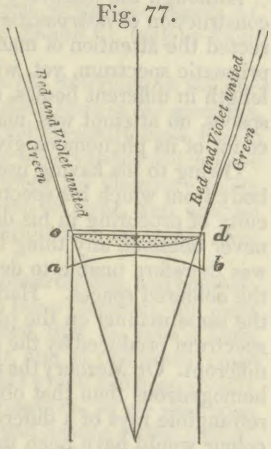


Fig. 78.

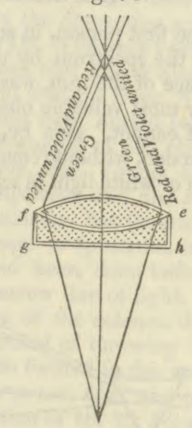
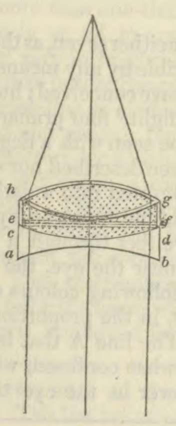


When these two compound lenses are placed in contact, as shewn in fig. 79, it is manifest that the equal and opposite deviations of the green ray will balance each other, and that this ray will therefore be united with the red and violet, and thus form a pencil exempt from secondary colours. The plates of glass shewn by dotted lines at *ef*, *cd*, though necessary when the two compound lenses are separate, as in fig. 77, 79, are of course removed, since the two fluids which they separate, as fig. 78, are the same. Hence the compound object-glass, consists of a concave lens of crown glass *ab*, of a meniscus *ef*, of a fluid, and a convex glass of another fluid, enclosed in two glasses like watch-glasses. Dr. Blair found it best in practice to make all the glasses concave meniscuses in place of having all the concavity in one lens *ab*.

Fig. 79.



In continuing his experiments, Dr. Blair happened to try the muriatic acid mixed with a metallic solution; he found it best to make his compound convex lens, as shewn in fig. 78, of crown glass, and that fluid which enabled him to correct the colour of the compound concave in fig. 77, and likewise to correct the aberration of figure by a concave which lengthens only by one-third the focal distance of the convex.

When he was trying a compound concave formed only of crown glass and muriatic acid, he observed that this fluid produced an inverted secondary spectrum, and gave a primary spectrum, in which the green rays were among the most refrangible, and hence he was conducted to the idea of forming a compound lens consisting merely of a single concave lens of muriatic acid placed between a plano-convex and a meniscus of crown glass. In this lens, which he actually constructed and used, he observes *that the rays of different colours were bent from their rectilineal course with the same equality and regularity as in reflexion.*[1]

Fig. 80.

In such telescopes, Dr. Blair found that when the focal length of the object-glass was *nine inches,* the aperture might be increased as far as *three* inches; and in order to distinguish such instruments where the aberration is removed from *achromatic* ones in which it is only partially removed, he proposes the use of the term *aplanatic.*[2]

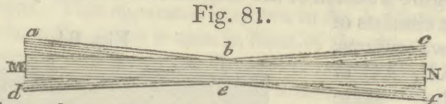
Sect. IV.—*On the tertiary spectrum, and the method of correcting the aberration of colour by prisms and lenses of the same kind of glass.*

Tertiary spectrum.

The existence of the *tertiary* spectrum was discovered experimentally by Sir David Brewster, who deduced it also from the constant ratio of the sines. It is produced when the dispersion of a prism of any substance is corrected by another prism of the same substance with a different refracting angle. An irrationality takes place in the coloured spaces, which prevents the correction of colour from being complete. The residuary spectrum was therefore called the *tertiary* spectrum merely to distinguish it from the *secondary* one, which is produced by the specific quality in the refracting media, which act in opposition to each other.

In examining the phenomena of this new spectrum, Sir David Brewster was led to a very paradoxical method of exhibiting it.

Fig. 81.



Having formed a prism of oil of cassia, with a large refracting angle, and viewing through it the broadest horizontal bar of a window, so that the edges of the bar were free of all colours, he inclined the prism so as to make the bar exhibit at its edges the prismatic colours, as shewn in fig. 81, where the edges *b*M and *e*N had spectra *ba*M, *ef*N, consisting of the usual *red* and *yellow* rays, while the edges *e*M, *b*N had spectra *ed*M, *bc*N composed of the usual blue and violet rays. These spectra increased from *b* and *e* towards M and N, and at the nodes *b*, *e*, where the spectra would have vanished, had each face of the prism received the rays symmetrically, the *tertiary spectrum* was clearly displayed in the form of a *green* and *purple* fringe.

In order to produce refraction without colour by two prisms of the same kind of glass, they may be combined, as in fig. 82, where a ray of light R incident on the first prism AB is refracted to the axis MF at F. The prism AB has a smaller refracting angle than CD, and is placed in an oblique position, so that its dispersion is increased in a greater ratio

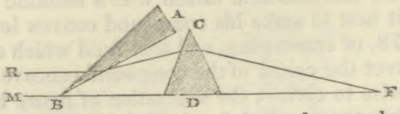
[1] *Edin. Trans.* vol. iii. p. 53.

[2] *Id. Id.*

Chromatics.

than its refraction, for the purpose of correcting the dispersion of CD without balancing its refraction; the prism CD having a position in which its refraction and dispersion are a minimum.

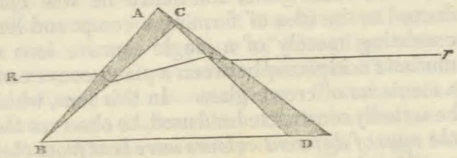
Fig. 82.



The ray R will therefore converge colourless, and meet the axis at F.

If the prisms have the same refracting angle, and are placed in the position shewn in fig. 83, the ray R will emerge colourless in the direction *r*. This combination of prisms, as well as that in fig. 82, has the property of expanding all objects viewed through them, in a vertical plane passing through their sections BACD, that is, of *magnifying them in one plane*. Hence, if we place another similar pair of prisms horizontally, this pair also will magnify objects in a horizontal plane, and by combining these two pair of prisms, we obtain an instrument which will expand or magnify objects in all directions.

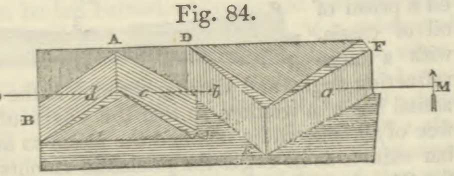
Fig. 83.



This instrument was first constructed by Sir David Brewster in 1812, under the name of a *teinoscope*, for altering the proportions of objects in plans and drawings, by expanding them differently in rectangular directions;[1] and there is reason to think that Dr. Blair was early acquainted with this method of magnifying objects by prisms. Mr. Archibald Blair a few years ago put into Sir David Brewster's hands an instrument of this kind, composed of four prisms which had been executed by his father, but the date of its construction he had no means of discovering. There cannot, therefore, be the shadow of a doubt that both the principles and the invention of an instrument for magnifying objects by means of prisms, were known and published in Scotland long before the celebrated M. Amici of Modena brought forward a contrivance of the same kind. That M. Amici's invention was an independent one will not be questioned.

As we conceive that a telescope of this kind may have many useful applications, we have given in the annexed figure a sketch of the instrument as actually fitted up for use. It consists of two prisms, AB, AC of the same kind of glass, and having a small refracting angle.

Fig. 84.



Their common line of junction at A is horizontal, and their planes of refraction vertical. Other two similar prisms DE, EF, are placed transversely, their common line of junction at E being vertical, and their planes of refraction horizontal. An object M, therefore, seen through the prisms in the direction OM, by an eye placed at O, will be magnified three, four, or five times, or more according to the inclination and angles of the prisms. It is expanded or stretched out in a horizontal plane by the two first prisms ED, EF, and then expanded and stretched out in a vertical plane by the other two prisms, AB, CD.

If we use homogeneous light, we may construct the instrument with only two prisms, as there is no necessity for correcting the colour with a second prism. For solar observations, the two prisms will constitute a telescope, a darkening glass being used as in other instruments. It will be thus equally useful for viewing the lines in the spectrum, where homogeneous light is necessarily used; and by placing two, three, or four instruments in the same tube, we may obtain any magnifying power we desire. The writer of this article is at present occupied with the construction of one of these instruments with rock salt prisms. The length of the instrument which we have drawn is only *two inches and three quarters.*

Prism Spec...

Sect. V.—*On the Optical Phenomena of the Spectrum.*

Phenomena of spectra.

Although the discovery of the principle, and the actual construction of *achromatic* and *aplanatic* telescopes had directed the attention of many observers to the nature of the prismatic spectrum, yet, with the exception of its varying length in different bodies, and the continuity of its coloured spaces, no attempt was made to question the general account of its phenomena given by Sir Isaac Newton.

Owing to his having used the diameter of the sun as the body from which his spectrum was formed, and to the difficulty of procuring in his day good prisms of glass, Sir Isaac never obtained any thing like pure homogeneous light, and was therefore unable to determine the exact boundaries of the coloured spaces. Had the spectrum been observed in the same manner on the planet Mercury and on Saturn, the spectrum produced by the same prism would have been very different. On Mercury the rays would have been less pure and homogeneous than that observed on our earth, and the mean refrangible rays of a different colour; while on Saturn the colour would have been more pure and homogeneous.

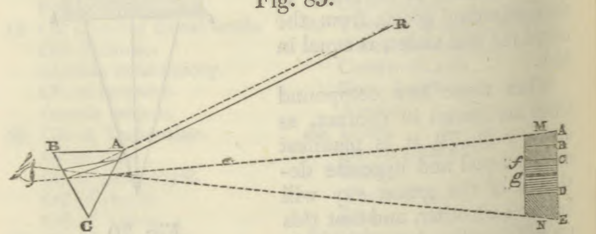
1. *Discoveries of Dr. Wollaston.*

Discoveries of Dr. Wollaston.

The first person, in so far as we know, who proposed to form the spectrum by using *a very narrow pencil of light* in place of the sun, was Dr. Wollaston, to whom we owe many most valuable observations on the subject.

"I cannot," says he, "conclude these observations on dispersion, without remarking, that the colours into which a beam of white light is separable by refraction, appears to me

Fig. 85.



to be neither seven, as they usually are seen in the rainbow, nor reducible by any means (that I can find) to three, as some persons have conceived; but that by employing a very narrow pencil of light,[2] four primary divisions of the prismatic spectrum may be seen with a degree of distinctness, that I believe has not been described nor observed before. If a beam of daylight be admitted into a dark room by a crevice $\frac{1}{20}$ of an inch broad, and received by the eye at the distance of ten or twelve feet through a prism of flint glass, *free from veins*, held near the eye, the beam is seen to be separated into the four following colours only, *red*, *yellowish green*, *blue*, and *violet*, in the proportions represented in the figure.

"The line A that bounds the *red* side of the spectrum is somewhat confused, which seems in part owing to the want of power in the eye to converge red light. The line B,

[1] *Edinburgh Phil. Journal*, vol. vi. p. 334, April 1822.

[2] See p. 406.

Prismatic Spectrum.

between red and green in a certain position of the prism, is perfectly distinct; so also are D, and E, the two limits of violet. But C, the limit of green and blue, is not so clearly marked as the rest; and there are also, on each side of this limit, other distinct dark lines, *f* and *g*, either of which, in an imperfect experiment, might be mistaken for the boundary of these colours.

"The position of the prism in which the colours are most clearly divided, is when the incident light makes about equal angles with two of its sides. I then found that the spaces AB,BC,CD,DE, occupied by them, were nearly as the numbers 16, 23, 36, 25." Dr. Wollaston adds, that when the inclination of the prism is altered so as to increase the dispersion of the colours, the proportions of them to each other are then also changed, so that the spaces AC and CE, instead of being as before 39 and 61, may be found altered as far as 42 and 58.

The lines which Dr. Wollaston has described in the preceding observations, are called the *fixed lines in the spectrum*, and may be considered, as we shall presently have reason to see, as one of the most valuable observations which have been made on this subject. He owed the discovery solely to his having used a *narrower* line of light, and had he employed a still narrower and brighter line, he would have seen many more lines.

In considering Dr Wollaston's observations, and comparing the results with those of Sir Isaac Newton, we must carefully attend to the circumstance, that he used *a beam of day-light*, not one of sun-light, and as this beam emanated from the blue sky, and was light which had been greatly modified by the action of the atmosphere, as we shall soon show, his estimate of the number and nature of the coloured spaces, does not in the least affect or invalidate the observations of preceding authors. The sun's light used by Newton had lost many of its rays, by the absorptive action of the atmosphere, before it fell upon Dr. Wollaston's prism. In consequence of taking it for granted that Dr. Wollaston was analysing the same kind of light that Sir Iasac Newton analysed, both he and Dr Young were misled in the interpretation of the phenomena. Speaking of the observations of Newton and his followers, Dr. Young says, "The observations were however imperfect, and the analogy was wholly imaginary. Dr Wollaston has determined the division of the coloured image or spectrum, in a much more accurate manner than had been done before: by looking through a prism, at a narrow line of light, he produces a more effectual separation of the colours, than can be obtained by the common method of throwing the sun's image on a wall. The spectrum formed in this manner consists of four colours only, *red*, *green*, *blue*, and *violet*, which occupy spaces in the proportion of 16, 23, 36, and 25, respectively, making together 100 for the whole length; the red being nearly one-sixth, the green and the violet each about one-fourth, and the blue more than one-third of the length. The colours differ scarcely at all in quality within their respective limits, but they vary in brightness; the greatest intensity of light being in that part of the green which is nearest to the red. A narrow line of *yellow* is generally visible at the limit of the red and green; but its breadth scarcely exceeds that of the aperture by which the light is admitted, and Dr. Wollaston attributes it to the mixture of the *red* with the *green* light. There are also several dark lines crossing the spectrum within the blue portion and in its neighbourhood, in which the continuity of the light seems to be interrupted. This distribution of the spectrum Dr. Wollaston has found to be the same whatever refracting substance may have been employed for its formation; and he attributes the difference, which has sometimes been observed in the proportion, to accidental variations of the obliquity of the rays." Hence Dr. Young was led to suppose that the *yellow* line was the accidental union of the extremity of the *red* and *green* spaces,—to regard *yellow* as a mixture of *red* and *green* light, and to suppose that the *green space* consisted only of homogeneous green without any mixture of yellow. "In consequence," says he, "of Dr. Wollaston's *correction* of the description of the prismatic spectrum compared with these observations, it became necessary to modify the supposition that I advanced in the last Bakerian lecture respecting the proportions of the sympathetic fibres of the retina; *substituting* RED, GREEN, and VIOLET, for RED, YELLOW, and BLUE." In this manner the *yellow* space was struck out of the spectrum on the authority of Dr. Wollaston's observations!

2. *Discoveries of Fraunhofer.*

Discoveries of Fraunhofer.

Without knowing any thing of the discovery of fixed lines in the sky light by Dr. Wollaston, M. Fraunhofer, a celebrated practical optician at Benedictbaiern near Munich, made a series of the most beautiful discoveries respecting the spectrum, which he published in 1814 and 1815. By making use of prisms of uniform density, and entirely free of veins, and by excluding all extraneous light, and stopping the rays which formed the coloured spaces which he was not examining, he made the important discovery that the *solar* spectrum was covered with a great number of black lines of different thicknesses parallel to each other, and perpendicular to the length of the spectrum. Lines in the spectrum.

All kinds of prisms, fluid or solid, provided they were good, exhibited the same lines, and Fraunhofer found, that these lines had a fixed position in the spectrum, and that they varied with the length of the spectrum, the distance between any two affording a precise measure of the action of the prism on the rays in which these two lines were placed. These lines are darker than the rest of the spectrum, and some of them appear entirely black. The largest lines could scarcely be seen if the aperture exceeded *a minute*, and the finest lines also disappeared entirely when the aperture was 40″. The aperture used by Fraunhofer was 36″ high, and 15″ wide, that is, at a distance of 24 feet from the aperture. It was nearly one-fiftieth of an inch wide, and 2.88 inches high. The prism was made of flint-glass, had a refracting angle of nearly 60°, and was placed before the object-glass of the telescope, so that the angles of incidence and emergence were equal, or the angle of refraction a *minimum*. This apparatus is shewn in fig. 1, Plate CCCLXXXI, where the prism is seen in front of the object-glass of the telescope of a repeating theodolite resting on a horizontal plane with a steel axis round which it moves. The box on which the axis turns is firmly united with the telescope. Plate CCCLXXXI. Fig. 1.

When the prism was turned round, so as to increase the angle of incidence, the lines disappeared, and the same took place when the angle of incidence was diminished. But the lines reappeared at a greater incidence by shortening, and at a smaller incidence by lengthening the telescope.

The *solar prismatic spectrum*, as seen by Fraunhofer, is represented in fig. 2 of Plate CCCLXXXI which has been abridged, and many of the lines necessarily omitted, Fraunhofer himself, having been obliged to leave them out of his map. At the line A the *red* space nearly terminates, and the violet space at I; but when the light of an illuminated cloud fell upon the aperture in the prism, the spectrum appeared to terminate on one side at B, and on the other between G Fig. 2.

Dr. Young has given in his Elements of Nat. Phil. vol. 1. p. 786, plate 29, a small coloured drawing of the spectrum as seen by Dr. Wollaston and himself, with the *yellow* line. This line has no existence in the true solar spectrum.
Nat. Phil. vol. ii. p. 637.

Prismatic Spectrum.

and H. At A there is a distinct and well defined line, the boundary of the red space being a little beyond it. "At *a* there is a mass of lines, forming together a band darker than the adjacent parts. The line at B is very distinct, and of a considerable thickness. From B to C may be reckoned nine very delicate and well defined lines. The line at C is broad, and black like D. Between C and D are found nearly 30 very fine lines, which, however, with the exception of two, cannot be perceived but with a high magnifying power, and with prisms of great dispersion; they are besides well defined. The same is the case with the lines between B and C. The line D consists of two strong lines separated by a bright one. Between D and E we recognise about 84 lines of different sizes. That at E consists of several lines, of which the middle one is the strongest. From E to *b* there are nearly 24 lines. At *b* there are three very strong ones, two of which are separated by a fine and clear line. They are among the strongest in the spectrum. The space *b*F contains nearly 52 lines, of which F is very strong. Between F and G there are about 185 lines of different sizes. At G many lines are accumulated, several of which are remarkable for their size. From G to H there are nearly 190 different lines. The two bands at H are of a very singular nature. They are both nearly equal, and are formed of several lines, in the middle of which there is one very strong and deep. From H to I they likewise occur in great numbers, Hence it follows that, in the space BH, there are 574 lines. The relative distances of the strongest lines were measured with the theodolite, and placed in the figure from observation. The faintest lines only were inserted from estimation by the eye." The lines in the solar spectrum which we have thus minutely described after Fraunhofer, are not seen in the spectra formed by any white flame, or white light, whether it is generated by ordinary combustion, or produced by the application of intense heat to a solid body. In the flame of a lamp, however, Fraunhofer discovered that there is a double yellow line occupying *exactly* the same place as the double line D, the two black lines of D corresponding with the two luminous ones of the double yellow line in lamp light. Hence it follows that ordinary *white* light, produced in the manner already mentioned, has 590 rays of a definite refrangibility which do not exist in solar light, and hence the black lines have been called *defective rays* or *lines*.

"Various experiments," says Fraunhofer, "and changes to which I have submitted these lines, convince me that they have their origin in the nature of the light of the sun, and that they cannot be attributed to illusive observations, or any other secondary cause."

By means of the apparatus shewn in fig. 1, Plate CCCLXXXI, Fraunhofer determined in a very accurate manner the distances between the principal fixed lines[1] B, C, D, E, F, G, H, taking those which divided the spectrum most conveniently. The line *b* for example, would have been better than E for its magnitude and distinctness, but it does not divide the space DF so equally. He repeated these observations with different kinds of flint and crown glass of several fluids, and obtained the results given in the following table.

Table, shewing the Distances of the Principal Fixed Lines in the Spectrum, in various Media, according to Fraunhofer.

These valuable data were deduced from measures taken *six* times for each substance; but as the theodolite was only twenty-four feet distant from the window of his dark room, it became necessary to apply a correction to the angle of deviation μ, arising from the distance 4·25 inches of the centre of the prism from the axis of the theodolite. This correction would have been very great for twenty-four feet, and therefore Fraunhofer, to avoid the uncertainty which

[1] The reader will be desirous of knowing, which of these principal lines were discovered by Dr. Wollaston. The following attempt to do this is given by Sir David Brewster in his Report on Optics, published in the Proceedings of the British Association, vol. i. p. 320, note 2. In the spectrum formed by a narrow beam of day-light, Dr. Wollaston had previously to the year 1802, discovered *seven* lines, which he has designated by the letters A, B, *f*, C, *g*, D, E, the first line A being, according to his observations, the extreme boundary of the red rays, and the last line E the extreme boundary of the *violet* rays. The correspondence of these lines with those of Fraunhofer, I have with some difficulty ascertained to be as follows—

A, B, *f*, C, *g*, D, E Wollaston.
B, D, *b*, F, G, H. Fraunhofer.

There is no single line in Fraunhofer's drawing in the spectrum, (nor is there any in the real spectrum) coincident with the line C of Wollaston; and indeed he himself describes it as not being "so clearly marked as the rest." I have found, however, that this line C corresponds to a number of lines half way between *b* and F, which, owing to the absorption of the atmosphere, are particularly visible in the light of the sky near the horizon. In order to have seen the lines B and H of Fraunhofer, especially the last, Dr. Wollaston's "beam of day-light" must have come from a part of the sky very near the sun's disc.

arises from a great correction, determined the angle μ for the yellow ray of the light of a lamp which has the same refrangibility as D. When the lamp was placed at the distance of 692 feet, the correction of μ for crown glass and water was only 40″. Hence for the smaller arcs, which were really measured, the corrections were very small, being only 2″·5 for BC, 6″·5 for CD, and 8″ for DE. All the angular distances, therefore, in the preceding table have had this correction applied to them.

M. Fraunhofer then proceeded to determine the index of refraction m for the different fixed lines, and calling σ the angle of incidence, ρ the angle of emergence, ψ the angle of the prism, and m the index of refraction he obtained,

$$m=\sqrt{\left(\frac{(\sin.\ \rho+\cos.\ \psi\ \sin.\ \sigma)^2+(\sin.\ \psi\ \sin.\ \sigma)^2}{\sin.\ \psi}\right)}$$

When the angle of incidence is equal to the angle of emergence, or the angle of deviation a *minimum*, and if μ is the angle of deviation, or that which the emergent ray forms with the incident ray, we have

$$m=\frac{\sin.\ \frac{1}{2}(\mu+\psi)}{\sin.\ \frac{1}{2}\psi}.$$

When the dispersive power of the body under examination is very great, the value of the index of refraction m given by this last formula will not be rigorously correct, as the equality of the angles of incidence and emergence can only take place for one ray. Fraunhofer, therefore, measured the distances BC, CD, or when the distance of the two lines B and C, C and D was the smallest, which takes place when the ray or line which bisects these spaces has its angle of incidence and emergence equal. When the substances have a less dispersive power, or the prisms a smaller angle, the same care is not necessary to obtain this degree of accuracy. If we then call Em the index of refraction for the ray E, we have

$$Em=\frac{\sin.\ \frac{1}{2}(\mu+\psi+DE)}{\sin.\ \frac{1}{2}\psi}.$$

and for the ray F,

$$Fm=\frac{\sin.\ \frac{1}{2}(\mu+\psi+DE+EF)}{\sin.\ \frac{1}{2}\psi}.$$

In this way Fraunhofer obtained the following indices of refraction for the different solids and fluids formerly used:—

Illuminating power of the spectrum.

Before he proceeded to employ these results to the construction of achromatic telescopes, Fraunhofer endeavoured to determine by exact measurement the illuminating power of the spectrum at different points. In order to do this, he constructed an apparatus represented in figs. 3 and 4, Plate CCCLXXXI. To an eye-glass E, made on purpose for the telescope of the theodolite, he applied a small plane metallic mirror a, the edge of which being well defined, cut the field of the telescope in the middle, as shewn in the figure. It was placed at an angle of 45° to the axis of the object-glass A, and in its focus. The eye-glass E is pulled out till the edge of the small speculum a is distinctly seen. At the side of the eye-glass, and in a direction at right angles to the edge of the speculum a, or to the axis of the telescope, he fixed a tube bcB, cut at the point b in the direction of its length, and in this opening he placed a narrow and a shorter tube MN, whose section is seen at b, crossing the larger tube cB at right angles. A small flame, supplied with oil from an external vessel, was placed in the tube MN, so as to be in the axis of the tube cB. At the point of the narrow tube b or MN, where it was cut by the axis of the tube cB, was a small round aperture for allowing the light of the flame to fall upon the speculum a. Hence it follows that the eye at E will see in half of the field the speculum a illuminated by the flame, and in the other half the colours of the spectrum formed by a prism placed, as formerly described, before the object-glass A. By making the tube MN and the flame approach the speculum, we increase its degree of illumination, and can therefore make it equal to the illumination of the part of the spectrum which we wish to determine. In this way he obtained for each coloured space in the spectrum a certain distance of the flame from the speculum, which afforded a measure of the intensity of illumination, the squares of the distances being inversely as the intensities.

"Though at first sight," says Fraunhofer, "it appears difficult to compare the light of two different colours, yet it becomes easy by a little practice. The intensity of the light of the mirror approaches more to that of any colour in the spectrum, if at the same position of the eye-glass its vertical margin is less distinct. If the mirror is adjacent to a part of the spectrum more or less illuminated, the edge of the mirror becomes, in both cases, more distinct; because, in the first case, the mirror appears to be placed in the shadow, and in the second case, it is the colour of the spectrum that is found there. The experiment with the mirror is a little difficult and uncertain, if we perceive clearly the lines of the spectrum, because the brightest and the darkest lines touch one another almost in every colour. On this account the aperture in the window-shutter is made so broad, that only the strongest lines are just visible, and the fine ones not at all. In place of the mirror outside of the shutter by which the light entered, I put a white plane surface illumi-

Prismatic Spectrum.

nated by the sun, because by any imperfection of the mirror the light is irregularly dispersed, which renders the observations more dubious.

"In order to vary the experiments, I at one time enlarged the round aperture before the flame, and at other times I contracted it. I placed also at the end *c* of the wide tube a piece of ground glass, through which the mirror received its light. In this case I measured the distances of the flame from the ground glass. To avoid all illusion, the aperture before the eye-glass ought to be small, and to be at the place where the principal rays, or the axes of the rays coming from the edge of the field, cut the axis of the telescope. With the prism of flint glass, No. 13, having an angle of $26^\circ 24' 5$, I obtained the following results. Though the experiments were made in clear weather, and at noon, I sometimes perceived, in the course of the observations, a slight change in the density of the light which the prism received. The differences in the four sets of experiments may have been partly owing to this change, and the flame may also have changed its intensity in the course of the observations. If we call the intensity of the light at the brightest part of the spectrum 1, we shall then have,"—

Table, shewing the Intensity of Illumination at different points of the Spectrum.

Points of the Spectrum where the illumination was measured.	Intensity of light.	Intensity of light.	Intensity of light.	Intensity of light.	Mean Intensity, by four experiments.

Fraunhofer found the brightest part of the spectrum at the distance of nearly one-third or one-fourth of DE from D.

Plate CCCLXXXI.

The results of the preceding experiments are expressed in the curve, fig. 5, which accompanies the spectrum in fig. 2, the preceding values in the last column of the table being the ordinates of the curve, and the angular distances BC, CD in the table in page 416, for flint glass, No. 13, being the abscissæ.

If we suppose that the quantity of the light in the differently coloured spaces is represented by the areas of the curves BC, CD, we shall obtain the following results, the area of the space DE being made equal to unity.

	Quantity of light in, or area of,
BC............	0·021
CD............	0·300
DE............	1·000
EF............	0·328
FG............	0·185
GH............	0·035

M. Fraunhofer next proceeds to apply these interesting results to the construction of achromatic combinations for telescopes. From the results in the table in p. 416, he obtains the following ratios of the different dispersive powers of the differently coloured rays in the different combinations mentioned in the first column. Achromatic combinations.

Table, shewing the Ratios of the Dispersion of the differently coloured rays for each combination of Media.

ismatic ectrum.

The important results embodied in the preceding table, completely overturn the opinion of Dr. Wollaston respecting the proportionality of the different colours, and establish beyond all question the *irrationality* of the coloured spaces. In the very first combination, for example, of *flintglass* and *water*, the ratio of the dispersion of the rays in the *red* space BC, is as 1 to 2·56, whereas in the *violet* space GH, it is as high as one to 3·726. In the combination of *flint glass* and *oil of turpentine*, we have a case where the irrationality is very trifling, and what Fraunhofer has not observed, the irrationality is nothing between the *orange* and *blue* spaces, and almost nothing between the *red* and *indigo*, but very considerable between the *green* and all the other spaces, and a maximum between the green and the violet. The differences of the ratios, too, are *negative* or diminishing in the two first or least refrangible spaces, and *positive* in all the rest, the *negative* differences nearly balancing the *positive* ones; whereas, with very trifling exceptions, the ratios increase towards the most refrangible extremity of the spectrum.

It is obvious that in the construction of achromatic object-glasses of flint and crown glass, there must always be a considerable portion of outstanding colours or *aberrations*, as Fraunhofer calls it. Hence in place of making the focal lengths of the two lenses in the exact ratio of their dispersive powers, we must alter the ratio so as to make the outstanding colours a minimum for the distinct vision of objects. But in order to do this, we must take into account the intensity of illumination in the coloured spaces; for it is obvious that a given irrationality in the yellow spaces, will, from the intensity of its illumination, be much more regarded than a similar irrationality in the violet space. As the outstanding rays, therefore, will be injurious to distinct vision in proportion to their intensity, the distinctness will be a maximum, as Fraunhofer has shewn, when the ratio of dispersion x is taken, such that

$$x=\frac{b\beta+c\gamma+d\delta+e\epsilon+f\xi+g\eta}{\beta+\gamma+\delta+\epsilon+\xi+\eta}$$

in which case we have

$$(x-b)\,\beta+(x-c)\gamma+(x-d)\delta+(x-e)\epsilon+(x-f)\xi+(x-g)\eta=0$$

where β, γ, δ, ϵ, &c. express the quantity of light in the spaces BC, CD, DE, &c. and b, c, d, e, &c. the quotients or ratios of dispersion $\frac{\mathrm{C}m'-\mathrm{B}m'}{\mathrm{C}m-\mathrm{B}m}$, $\frac{\mathrm{D}m'-\mathrm{D}m'}{\mathrm{D}m-\mathrm{B}m}$ &c.

This ratio, or the value of x calculated for *flint glass*, No. 30, and *crown glass*, No. 13, is as 1 to 2·012; but Fraunhofer found that in an object-glass, consisting of these two kinds of glass, the distinctness was a maximum when the ratio was as 1 to 1·98.

Fi lines in light.

To the Chevalier Fraunhofer we owe also the discovery of fixed lines in the light of the planets and fixed stars. As the light of our sun is defective in so many rays, it was to be expected that the light of all the planets which he illuminates, would be equally defective in the same rays. In the brighter colours of the *Moon's* spectrum, we find the same fixed lines as in the sun's light, and in the same place. The spectra from the light of *Mars* and *Venus* contained the lines D, E, *b*, and F, of solar light, and precisely in the same place. In the spectrum of *Sirius* he was unable to perceive fixed lines in the *orange* and *yellow* colours, but in the *green* he saw a very strong streak, and in the *blue* other two very strong ones, having no resemblance to any of the lines in the solar spectrum. *Castor* gives a spectrum resembling that of *Sirius*. The streak in the green was so intense, that notwithstanding the weakness of the light, yet he ascertained by measurement that it occupied the same place as the green streak in Sirius. He distinguished also the two streaks in the blue, but he could not ascertain their place. In the spectrum of *Pollux* he found many weak and fixed lines, which resembled those of *Venus*. The line D he saw distinctly, and occupying the same place as in the pure light. In the spectrum of *Capella*, he saw the lines D and *b*, as in solar light. The spectrum of *Betalgeus* contains numerous fixed lines, which in a favourable atmosphere are sharply defined. There were lines like the solar ones D and *b*. In the spectrum from *Procyon*, some lines were perceived with difficulty, but they were not sufficiently distinct to be measured. In the orange space, however, he saw a line at D.

Prismatic Spectrum.

Sect. VI.—*On the Physical Properties of the Spectrum.*

Physical properties of the spectrum.

The physical properties of the spectrum, which have been the subject of experimental investigation, are its *heating* power, and the *chemical* and apparently *magnetical* influence of its rays.

Heating power.

Heating power of the spectrum. That the heat of the coloured rays should be most intense where their light was strongest, was long the general belief of philosophers; and Landriani Rochon,[1] and Sennebier, found by direct experiment that the highest temperature existed in the *yellow* space. Sir W. Herschel, however, found that the heating power increased from the *violet* to the *red* space, and that the thermometer continued to rise when placed beyond the visible red extremity of the spectrum. He therefore drew the conclusion that there were invisible rays in the light of the sun which had the power of producing heat, and which had a less degree of refrangibility than red light. Sir W. Herschel attempted, in vain, to determine the index of refraction of the extreme invisible ray which possesses the power of heating; but he ascertained that at a point one-and-a-half inches distant from the extreme red ray, the invisible rays exerted a considerable heating power, even though the thermometer was placed at the distance of fifty two inches from the prism.

Sir W. Herschel.

Sir Henry Englefield.

In 1801, Sir Henry Englefield repeated these experiments; but he does not acquaint us with the kind of glass of which his prism was made. He obtained the following results, which confirm those of Sir William Herschel.

Colours of the Spectrum.	Temperature, Fahr.
Blue	56
Green	58
Yellow	62
Red	72
Beyond Red	79

From our author's own account of the method of making these experiments, we place no confidence in the principal result respecting the invisible rays. "*As I had nothing to do with light*," says he, "it was not necessary to darken the room; and as I wished to accumulate as large a portion of solar heat as possible, *I placed the prism in an open window*." As the whole interest of these experiments was concentrated in the determination of *invisible* heating rays, Sir Henry had a great deal to do with light, as the whole question turned upon an exact appreciation of the *termination of the spectrum*. In a dark room the spectrum is much longer than in open day, and we have reason to believe from experiment, that Sir Henry Englefield's spectrum did not visibly extend beyond the line C of Fraun-

[1] The Abbé Rochon used a prism of flint glass, and a thermometer containing spirits of wine, and he found the maximum temperature in the *yellow orange* rays See his *Opsucules*, 1783.

Dr. Hutton, in his *Philosophy of Light and Heat*, Edin. 1794, p. 38, remarks that, "the compound light which is *white*, has a greater power of giving vision in proportion to its power of exciting heat; whereas in the *red* species, it is the opposite, for here the power of exciting heat is great in proportion to its power of giving vision."

Prismatic Spectrum

hofer, so that his maximum temperature of 79° was actually found in the red rays.

Recent experiments.

With the view of throwing light upon this subject, Sir David Brewster has endeavoured to ascertain the visible extent of the spectrum by various methods of condensing the light, and absorbing by coloured media, the luminous parts of the spectrum. By these means he has traced the visible spectrum, and the fixed lines in it as far beyond the line A as the distance of the group of lines *a* is from A, and has seen it indistinctly to a distance as great as AB beyond A. Hence there cannot be the least doubt that the experiments beyond the visible red were actually made when the thermometer was placed in the red space. He does not, however, conclude from this that there are no invisible rays beyond the red; but merely that the experiments of Herschel and Englefield were made in a part of the spectrum where rays of light actually exist. On the contrary, our author concludes that there are rays of heat of all degrees of refrangibility, and consequently consisting of waves of all degrees of breadth and velocity. When produced by a slight vibratory movement, the waves of heat are broad and slow; as the temperature rises they become narrower and quicker in their motion. When their velocity is such as to equal that of the extreme red ray, they become faintly visible, and the other colours are successively produced by quicker motion, till white light is radiated. This seems to be the process by which incombustible bodies are gradually raised from the deepest red to the brightest white; and if we examine, by means of a prism, the changes which take place in the gradually increasing light, we shall find that the different rays of the spectrum are successively added to the red light.[1] He conceives, therefore, that the sun emits rays of all degrees of refrangibility, extending probably far beyond the visible extremity of the violet, and though not capable of being rendered sensible, yet exercising powerful influences in the economy of nature.

Berard.

M. Berard, and Sir Humphry Davy obtained results analogous to those of Sir W. Herschel; M. Berard finding the maximum heat at the very extremity of the red ray, and Sir H. Davy beyond it.

Wunsch.

The most valuable series of experiments on this subject, were made by Professor Wunsch, and Dr. Seebeck of Berlin. So early as 1807, Professor Wunch[2] had made experiments with *prisms* of various substances, and obtained the following results:

Substances of which the Prisms were made.	Place of maximum heat.
Alcohol	Yellow space.
Oil of turpentine	Yellow space.
Water	Yellow space.
Green glass	Red.
Yellow glass	Extreme red.

Seebeck.

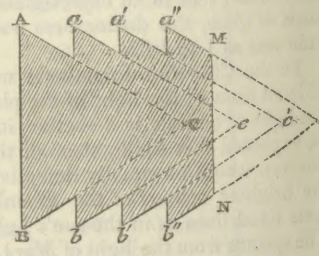
These results were confirmed by Dr. Seebeck, who obtained the following new results:

Substances of which the prisms are made.	Place of maximum heat.
Sulphuric acid concentrated	Orange.
Solution of sal-ammoniac	Orange.
Solution of corrosive sublimate	Orange.
Crown glass	Middle of red.
Plate glass	Middle of the red.
Flint glass, English	Beyond the red.
Flint glass, Bohemian	Beyond but nearer the red

The explanation which was given of these results, (which had been ascribed to different prisms of refracting caloric,[3]) by Sir David Brewster, accounts in a very satisfactory manner for all the phenomena. He conceives that transparent bodies have the same power of absorbing or stopping certain rays of the thermometric spectrum, as Dr. Robison called it, in the same manner as *coloured* bodies have the power of stopping certain rays of the luminous spectrum. These last bodies necessarily became coloured by stopping certain rays; but as the eye is not sensible to heat in the same manner as to light, the absorptive power of transparent bodies for heat can only be proved by the thermometer. He considers *water* as the type of bodies which are uniformly transparent for heat, as its maximum of heat coincides with its maximum of light. A prism of crown glass, on the contrary, is less uniformly transparent for heat; and its maximum of heat is in the red space, because it has absorbed much of the heat in the yellow space. In like manner flint glass has absorbed more of the heating rays in the red than the crown glass, and hence its maximum is about the extremity of the red, or beyond the end of the spectrum as commonly seen. In coloured media the maximum ordinate of their luminous spectrum, shifts along the whole prismatic spectrum; sometimes there are *two* or *more maxima* of light, and sometimes narrow and wide spaces entirely defective in light. Hence Sir David Brewster[4] supposes that there are defective spaces, and lines in the thermometric spectrum.

This view of the subject suggests a new mode of investigating the phenomena of the heating rays. If we take a prism of coloured glass to investigate the dark spaces and lines produced by absorbing media, we shall only have a very imperfect approximation to the true result; that is, we never could have absolutely dark spaces in the spectrum, as long as all the rays that went to the formation of the spectrum, passed through *all the different thicknesses of the prism*. The thinnest parts of the prism allow all the rays to pass, and consequently illuminate the whole spectrum, so that the actions of various thicknesses of the media are confounded, and the real absorptive action at a given thickness concealed. In like manner in the spectrum of heat, the heating rays which pass through the thin parts of the prism, will throw heat into every part of the spectrum; and hence the experiments should be made with the frustums of prisms, where the difference of thickness is small, and the want of area made up by an increased height of the prism. The best way, however, of making the experiments, would be to use a compound prism constructed as in the annexed figure, where AB, MN, is the section of a compound prism consisting of four frusta of prisms, AB, *ab*, *a'b'*, &c. the frustum AB, being part of a prism ABC. the frustum *ab*, part of a prism *abc*, &c. or this compound prism, in place of being ground out of the mass, which would be difficult though practicable, might be composed of a single prism ABC, with parallel plates of the same glass added by cement so as to compose the notched parallelogram ABMN. Very interesting results might also be obtained by using spectra formed by interferences in the manner we shall afterwards describe.

Fig. 86.



In all experiments with fluid prisms, the results are perplexed with the effects of the plates of glass by which the prisms are confined, in the same manner as we would disturb and indeed nullify the results respecting the absorption of light

Prismatic Spectrum.

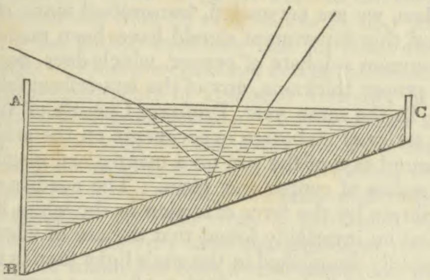
[Pri]smatic [Spe]ctrum.

by coloured fluids, were we to confine them in hollow prisms made of coloured glass. The only method of remedying this defect in the experiment, would be to form the spectrum by a prismatic vessel of the fluid, whose upper surface AC, is formed by gravity, and its lower surface BC, by a plate of highly polished silver, which reflects back the spectra through the first surface.

Fig. 87.



According to Berard's experiments, the calorific rays of the spectrum are capable of being doubly refracted and polarised like those of light, and he obtained the same result with culinary heat;—the heat of a dark body below redness, being substituted for solar heat.[1]

C[hem]ical eff[ect]s of th[e sp]ec-tr[um].

On the chemical effects of the spectrum. It was long ago observed by Scheele that muriate of silver was rendered much blacker in the violet rays of the spectrum, than in any other part of it.[2] In the year 1801, Professor Ritter of Jena exposed muriate of silver in various parts of the spectrum, and also beyond its apparent limits. He found that the action was least of all in the red rays, greater in the yellow, greater still in the blue and violet, and greatest of all beyond the *visible* violet rays. Dr. Wollaston and M. Beckman obtained a similar result, apparently without knowing what had been done by Ritter. In repeating the experiments of Scheele with white muriate of silver, "he found that the blackness extended not only through the space occupied by the violet, but to an equal degree, and to about an equal distance, beyond the visible spectrum; and that by narrowing the pencil of light *the discoloration may be made to fall* ALMOST ENTIRELY beyond the violet. It would appear, that this and other effects usually attributed to light, are not in fact owing to any of the rays usually perceived, but to *invisible* rays that accompany them; and that if we include two kinds that are invisible, we may distinguish upon the whole *six* species of rays into which a sunbeam is divided by refraction."[3]

M[uria]te of sil[ver].

The phrase *almost entirely* beyond the violet, used by Dr. Wollaston, cannot be considered as indicating the existence of invisible rays, even if we did not know from the experiments of Fraunhofer and others, that the visible violet space extends greatly beyond the place where both Ritter and Wollaston found the muriate of silver to be blackened. The existence of invisible rays, therefore, however probable, cannot be regarded as a scientific fact.

Gum [gu]ia-cum.

The chemical action of the least refrangible rays upon gum guiacum was discovered by Dr. Wollaston. Having washed a card with a solution of this gum in alcohol, he found that it acquired a *green* colour from the concentrated violet and blue rays. No change of colour was effected by heat; but in the red rays the tinged card lost its *green* and recovered its original colour. When the tinged card was placed in carbonic acid gas, the violet rays could not make it green; but when made green as before, it was speedily restored to its original yellow colour by the red rays. As Dr. Wollaston found that the back of a heated silver spoon restored the green colour as well as the red rays, we cannot attach any definite meaning to these experiments.

Prismatic Spectrum.

Hydrogen and chlorine

MM. Gay Lussac and Thenard discovered a very energetic chemical action of the solar rays. On exposing to a pencil of solar light, a mixture of hydrogen gas and caloric, in equal volumes, a detonation of the mixed gases took place, and hydrochloric and (muriatic acid) was formed.

M. Berard.

M. Berard repeated the experiments with muriate of silver, and with the preceding mixture of gases which he placed in the different coloured spaces of the spectrum, and he found that the chemical action was in every case more powerful towards the violet extremity and a little beyond it. M. Berard likewise concentrated the least refrangible half of the spectrum by means of a lens, and then the most refrangible half. The latter, though the most intense, produced no effect upon the muriate of silver, but the former blackened it in less than ten minutes.[4]

Mrs. Somerville.

Mrs. Somerville,[5] found that the chemical rays passed as freely through blue glass coloured with cobalt, as through colourless glass. Having dipped a piece of paper in a solution of muriate of silver, and cut it into two parts, one of them was placed under a blue glass, and the other under a white glass at the same instant. The one did not become black more than the other, and there was no difference in the intensity of their colour.

Dr. Young.

Dr. Thomas Young made a very interesting experiment with the view of determining if the invisible chemical rays interfered with the luminous ones. He produced the Newtonian rings with a thin plate of air, and having formed an image of them by means of the solar microscope, he threw this image upon paper dipped in a solution of nitrate of silver, and placed it at the distance of about nine inches from the microscope. "In the course of an hour," says he, "portions of three dark rings were very distinctly visible, much smaller than the brightest rings of the coloured image, and coinciding very nearly, in their dimensions, with the rings of violet light that appeared upon the interposition of violet glass. I thought the dark rings were a little smaller than the violet rings, but the difference was not sufficiently great to be accurately ascertained. It might be as much as one-thirtieth, or one-fortieth of the diameter, but not greater."[6]

M. Arago.

A more decisive experiment was afterwards performed by M. Arago, who formed a set of fringes, by the interference of two solar pencils, proceeding from a common origin, and having kept them very steadily for a long time upon the same part of a piece of paper rubbed with muriate of silver, a series of black lines were traced upon leaving their intervals, smaller than those of the dark and bright fringes formed by violet light.

Sir John Herschel.

In the summer of 1831, we had the satisfaction of being shewn by Sir John Herschel a very interesting experiment on the chemical action of the violet rays. When a solution of platinum in nitro-muriatic acid[7] is mixed with lime water, no precipitation to any considerable extent takes place in the dark, a slight flocky sediment only being formed after long standing. But if a fresh mixture, or an old one cleared by subsidence of this sediment, is exposed to the sun's rays, it instantly becomes milky, and a *white* precipitate is copiously formed. If the solution of platina is in excess, the precipitate is of a pale yellow colour. In the common light of a cloudy day, the same effect is produced more slowly. When tubes containing the mixture are exposed within red fluids, or even yellow ones which absorb the violet rays, no precipitation takes place.

The following remarkable facts were published in the *Journal de Pharmacie* for March 1832, but the abstract

Prismatic Spectrum.

from which we quote them, does not mention the name of the author.[1] A solution of peroxalate of iron, when kept in the dark or exposed to the heat of boiling water, suffers no change; but if it is exposed to the sun's rays, an infinite number of bubbles of carbonic acid are disengaged, and the solution is like a syrup undergoing strong fermentation.

A solution of muriate of platinum is decomposed by the oxalic acid, and the oxalates by the sun's light, with almost as energetic a disengagement of gas as the solution above mentioned.

Muriate of gold, when reduced by oxalic acid through the agency of light, covers the interior surface of the vessel with an uniform brilliant gilding, which is of a pure green colour by reflected light.

Oxalate of silver under water, is partially decomposed by solar heat (not by culinary heat) into metallic silver and carbonic acid. If the reddish brown solution of muriate of iridium in water, mixed with oxalic acid and heated to ebullition, is exposed to the sun, total discoloration promptly takes place, carbonic acid is disengaged, and grey metallic iridium precipitated.

Magnetic influence of the solar rays.

Magnetic influence of the solar rays.—Though many interesting and apparently accurate experiments have concurred to indicate the existence of this property of light, yet recent inquiries have thrown a considerable doubt upon the conclusions which have been drawn from them. Dr. Morichini, a Roman physician, first succeeded in 1813, in magnetising small needles, by making a focus of the violet rays, collected by a lens, pass repeatedly from the middle to one end of a needle, without touching the other half. By continuing this process for an hour, the needle had acquired distinct polarity. This experiment was repeated successfully by the Marquis of Ridolfi and M. Carpa; and Sir H. Davy and Professor Playfair, and other English philosophers, witnessed the successful performance of this experiment. Professor Configliachi at Rome, with the benefit of an Italian sun, M. Berard of Montpellier, and M. Dhombre Firmas at Alais, failed in obtaining similar effects from the violet rays, and hence the doctrine of the magnetic efficacy of blue light was exploded both by the French and Italian philosophers.

Mrs. Somerville.

In 1825 Mrs. Somerville repeated, in a different way, the experiments of Morichini. She took a slender sewing needle an inch long, quite devoid of magnetism, and having covered half of it with paper, she fixed it to the pannel of the wall with wax, so that its uncovered half should receive the violet rays of a spectrum formed by an equianglar prism of flint glass, whose refracting faces were each 1·4 by 1·1 inches, and which was placed about five feet from the wall. The needle was placed in a vertical plane nearly perpendicular to the magnetic meridian, and inclined to the horizon, and as the sun advanced to the meridian, the needle was moved parallel to itself to keep it in the sun's rays. In less than two hours, when the sun had just passed the meridian, the exposed half of the needle attracted the south and repelled the north pole of the magnetic needle. A second experiment on the same day confirmed this result, and similar effects were obtained by varying the circumstances of the experiment.

In the blue and green rays, the needles were magnettised but less frequently, and always after a longer exposure, but the magnetism was always as strong as in the violet. The indigo rays were nearly as efficacious as the violet. Pieces of clock and watch spring were also magnetised after longer exposure, and magnetic needles had their magnetism increased by the same means. When the violet rays were concentrated with a lens, the magnetism was sooner conveyed to the needle. When the halves of the needles and the pieces of spring were enveloped in violet and green silk, they became magnetic also. Mrs. Somerville does not seem to have tried as a check upon these results, the action of the *red* rays of the spectrum. The blue glass, we are persuaded, transmitted many of the red rays, and this experiment should have been made by using the common sulphate of copper, which does not transmit, with a proper thickness, any of the less refrangible rays.[2]

Professor Christie.

In the same year, Professor Christie of Woolwich, made a series of elaborate experiments on the action of the compound rays of the sun on a magnetised needle, and also on needles of copper and glass. The needles were caused to vibrate by the force of torsion in the white light of the sun, and he invariably found that the arc of vibration was more rapidly diminished in the sun's light than in the shade. Professor Christie regards these facts as proving incontestibly the existence of a magnetic influence in the solar rays, and tending to restore the credit of Morichini's experiments. He intended to make his needles vibrate under the separated rays of the sun, and had an apparatus prepared for the purpose; but we are not aware of his having either made these experiments or published any account of them.[3]

Baumgartner.

M. Baumgartner of Vienna,[4] while repeating the experiments of Mrs. Somerville, found that a steel wire, some parts of which were polished, while the rest were rough or without lustre, were magnetised by the action of the white light of the sun, each polished part exhibiting a *north*, and each unpolished part a *south* pole. By concentrating the sun's rays, the effect was produced more rapidly. On a wire eight inches long, he thus obtained eight poles. When the needles were perfectly oxidated or perfectly polished, or had polished lines in the direction of their lengths, he could not succeed in magnetising them.

Barlocci.

A less equivocal method of proving the magnetic influence of white light presented itself to Professor Barlocci. An armed natural loadstone capable of carrying a weight of 1½ Roman pounds (a Roman lb. is equal to 339·179 grammes) after *three hours* exposure to the strong light of the sun, was able to carry 2 oz. or one-sixth of a lb. more, and after an exposure of 24 hours its force was almost *doubled*. A second loadstone of nearly the same power was put into a dark place of the same temperature as that of the solar rays, but acquired no additional strength. A stronger magnet, which carried 5 lbs. 5 oz. and 2 deniers, was exposed to the light of a cloudy and humid atmosphere, and where it snowed; but it acquired no additional power; while, during the two subsequent days under a clear sky, its energy was more than doubled. The effect was not increased by a lengthened exposure.

Zantedeschi.

Among the most active labourers in this department of science, we must rank M. Zantedeschi of Pavia.[5] He had early obtained results similar to those of Morichini, and about the end of 1825, he had remarked, that suspended wire needles, devoid of all magnetism, and having one of their ends exposed to the white light of the sun under a glass receiver, turned that extremity to the north in the plane of the magnetic meridian. In repeating the experiment of Barlocci with artificial magnets, M. Zantedeschi found that a horse-shoe magnet, carrying 13½ ounces, carried 3½ oz. more after three days exposure to the sun, and by continued exposure, was able to carry 31 oz. He found also that the strength of oxidated magnets was increased by solar light, and that it diminished in those that were not oxidated. A loadstone, for example, not oxidated, lost 2½ oz. of its strength by three hours exposure to solar light, whilst another oxidated and similarly exposed, gained as much and even more strength. When the first was polished like a mirror, its strength suffered no change by a prolonged exposure to the

[Pri]smatic [Spec]trum.

[Pri]smatic sun. He likewise found that when a loadstone, whether oxidated or not, had its *north pole* exposed to the sun, it *acquired strength*, but *lost strength* when its south pole was exposed. In more than sixty experiments, the increase of strength varied from 1 to 2, and to 3½ oz. whereas the corresponding diminution was from 3½ to 5, and to 5½ oz. In these experiments our author confesses that he often encountered anomalies of which he could not detect the cause.

In repeating the experiments of Professor Christie, M. Zantedeschi obtained analogous results. Having placed a magnetic needle a foot long *in the shade*, he drew its place of rest through an arch of 90°, and it performed in 30″ four oscillations, the last of which had a semi-amplitude of 70°. When exposed *to the solar rays*, it performed in the same time, and under the very same circumstances, four oscillations, the last of which had only a semi-amplitude of 60°.

Ri[ess] and Mo[ser].

A great degree of doubt has been cast upon the conclusiveness of all these researches, by a series of well-managed experiments made recently by MM. Riess and Moser. The following experiments were made after the manner of Morichini. The needles were made of soft steel; their mass was very small, and they presented a considerable surface to the action of the light. The prism was placed in the position of minimum deviation, which corresponds to the greatest intensity of the light of the spectrum, the needles were placed on a graduated circle, three or four feet from the prism. The lens used had an aperture of 1·2 inches, and a focal length of 2·3 inches, and by it the focus of the violet rays was made to traverse one-half of the needle 200 times, excepting on the 10th July and the 12th August, when it was done only 100 times, and on the 25th July, when it was done 525 times. The following were the results which they obtained, shewing no change in the number of oscillations.

As *reflected* light was not used in Morichini's experiments, which our author wished to verify, they employed the *direct* light of the sun. In the experiments, however, with the needles *a*, *b*, *c*, they fixed the spectrum by means of a heliostate. They remark that the needle had been exposed 17½ hours to the action of the sun without becoming magnetic, whereas Morichini succeeded in magnetising his needles in from fifteen to thirty minutes.

These gentlemen repeated also in a similar manner the experiments of Baumgartner, but it would be unprofitable to detail them here, as they could not reproduce any of the results which he had obtained. They tried also the action of polarised light, but without any better success.[1]

Sect. VII.—*Recent Discoveries respecting the Spectrum.*

Prismatic Spectrum.

New analysis of the spectrum.

The analysis of white or compound light by the prism was made and perfected by Sir Isaac Newton; but though the prism could not decompose them, he committed a mistake in concluding that the colours of the spectrum were simple and homogeneous; "that to the same degree of refrangibility ever belonged the same colour, and to the same colour ever belonged the same degree of refrangibility." Now, though it is quite true that the *green* and *orange* colours of the spectrum cannot be decomposed *by the prism* into more simple ones, the one into *blue* and *yellow*, and the other into *yellow* and *red*, yet they can be decomposed by other means. This opinion respecting the compound nature of the colours of the spectrum, and the inability of the prism to analyse them, was first maintained by Sir David Brewster,[2] who, with the view of placing it beyond a doubt, undertook a series of experiments, in which he examined the effects produced on the solar spectrum by viewing it through a great number of coloured media, and reflecting it from coloured. By these experiments, he not only established the accuracy of his first opinion, that the *green* and *orange* colours of the spectrum were compound, the one consisting of *blue* and *yellow*, and the other of *red* and *yellow*, but was led to the more general result, that the whole spectrum was compound, consisting of three equal and superposed spectra of *red*, *yellow*, and *blue* light.[3] The following are the general results which he obtained:—

"1. White light consists of *three* simple colours, *red*, *yellow*, and *blue*, by the mixture of which all other colours are formed.

"2. The solar spectrum, whether formed by prisms of transparent bodies, or by gratings or grooves in metallic and transparent surfaces, consists of *three* spectra of *equal length beginning and terminating at the same points*, viz. a *red* spectrum, a *yellow* spectrum, and a *blue* spectrum.

"3. All the colours in the solar spectrum are *compound* colours, each of them consisting of *red*, *yellow*, and *blue* light in different proportions.

"4. A certain quantity of *white light*, incapable of being decomposed by the prism, in consequence of all its component rays having the same refrangibility, exists at every

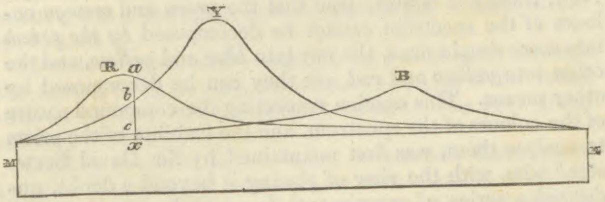
Prismatic Spectrum.

point of the spectrum, and may, at some points be exhibited in an insulated state.

"This remarkable structure of the spectrum will be better understood from figs. 88, 89, 90, which represent the three separate spectra, which are shewn in their combined state in fig. 91.

Fig. 91.



"In all these figures, the point M corresponds with the *red*, or *least refrangible* extremity of the spectrum, and N with the *violet* or *most refrangible* extremity; and the ordinates ax, bx, cx, of the different curves MRN, MYN, MBN, represent the intensity of the *red*, *yellow*, and *blue* ray at any point x of the spectrum.

"If the distance Mx in all these spectra be equal, then, in the combination of them shewn in fig. 91, the ordinates ax, bx, cx, will indicate the nature and intensity of the colour at any point x of the red spectrum. Thus, let

"The ordinate for *red* light $ax=30$,
yellow $bx=16$,
blue $cx=\ 2$,

$$ax+bx+cx=48 \text{ rays,}$$

then the point x will be illuminated with 48 rays of light, viz., 30 of red, 16 of yellow, and 2 of blue light.

"Now, as there must be certain quantities of red and yellow light which will form white, when combined with two blue rays, let us assume these, and suppose that white light, whose intensity is 10, will be formed by 3 red, 5 yellow, and 2 blue rays; hence it follows that the point x is illuminated by

"Red rays,.........27
Yellow rays,.......11
White light,......10

48 rays,

or, what is the same thing, the light at x will be *orange*, rendered brighter by a mixture of white light. The *two* blue rays, therefore, which enter into the composition of the light at x, will not communicate any blue tinge to the prevailing colour.

"If the point x is taken nearer M, and if, at that point, the *blue* rays are more numerous in proportion to the *yellow* than 2 to 5, that is, if they are as 3 to 5, then there will be one blue ray more than what is necessary to make white light with the two yellow and the three red rays, and this blue ray will give a blue tinge to that part of the spectrum, or will modify the peculiar colour of *pure red* light. In like manner, the *blue* extremity of the spectrum may have its peculiar colour modified by an excess of *red* rays, so as to convert it into *violet* light."

It would occupy too much space to bring forward the body of evidence which supports these views, and we must therefore refer our readers to the original memoir. We shall endeavour, however, in a few words, to prove the general principle of the compound character of the prismatic colours, by facts stated by persons who observed them, without any reference to this opinion. Sir Isaac Newton and Fraunhofer, and many persons besides, have, from long observation of the solar spectrum, concluded that there is a *homogeneous unmixed yellow*, and a *homogeneous unmixed orange* space in the spectrum. Newton makes the *yellow* space 40, and the *orange* 27, or 67 in all; while Fraunhofer makes the *yellow* space 27, and the *orange* space 27, or 54 parts of a spectrum whose length is 360 parts. Now, Dr. Wollaston declares that a beam of daylight is refracted by the prism into *five colours* ONLY, *red*, *yellowish green*, *blue*, and *violet*, and he defines their limits with his usual accuracy. Dr. Young, who repeated the same experiments with that exactness which was peculiar to him, declares that the spectrum formed in Dr. Wollaston's manner, consists of *four colours* ONLY, *red*, *green*, *blue*, and *violet*, "the colours differing scarcely at all in quality within their respective limits." Now both these accurate observers have rejected the *yellow* and *orange* spaces almost entirely, with the exception of the narrow line of yellow light formerly mentioned, thus running counter to all the observations of Newton and Fraunhofer. The cause of such a difference is this: The light analysed by Wollaston was the *blue light of the sky*, which had been deprived by absorption of many of its rays, having the same refrangibility as those which fell upon the prism. Dr. Young's *green* space was Sir Isaac Newton's *yellow* space, deprived of most of its *yellow* rays, and the *red* space adjoining the green was Newton's *orange* space, deprived by the absorption of the atmosphere, of almost all its yellow rays; and the sharp yellow line noticed by Dr. Young, and regarded by Dr. Wollaston as a mixture of red and green light, as if these spaces had overlapped a little, is part of the *orange* space of Fraunhofer and Newton, deprived of its *red* rays. This *yellow* band can be produced artificially upon all kinds of white light, and by the absorption of various media. Hence it is obvious, that by comparing the light reflected and modified by the *blue sky* with the direct *light of the sun*, we may obtain irrefragable proof of the compound nature of the yellow and orange spaces. That *red* light exists at the most refrangible extremity, is obvious from its *violet* colour; and that *blue* light exists at the *red* extremity, may be proved by the following observation of Sir W. Herschel.[1] He had occasion to view the prismatic spectrum, when reflected from clear turned brass, and he observes, "The colour of the brass *makes the red rays appear like orange*, and *the orange colour is likewise different from what it ought to be*." Here then, yellow light was seen at the very red end of this spectrum, and it was seen in consequence of *blue* light having been absorbed by the brass, because *blue* light mixed with the *orange*, observed by Sir W. Herschel, would alone recompose the original red. Here, then, there is a proof that *blue* light, and *yellow* light, and *red* light, all exist in the same place, at the least refrangible end of the spectrum. Effects similar to these may be produced by various coloured media, such as chemical solutions, or the coloured juices of plants; and by such means Sir David Brewster has succeeded *in insulating white light in the spectrum, incapable of being decomposed by the prism*. In a more recent memoir, "On the connexion between the phenomena of the absorption of light and those of thin plates,"[2] he has shewn that a separation of rays of different colours but equal refrangibility, is effected by the continued production of periodical colours by a number of thin plates acting successively upon the same pencil.

The existence of fixed lines in the spectrum, as discovered by Fraunhofer, was a fact unexampled in science. Various coloured bodies were known to absorb particular parts of the spectrum, and their peculiar colour was the necessary consequence of this absorption. Some of them, such as smalt blue glass, produced at a certain thickness several dark bands in the spectrum, but these bands shaded off by

[1] *Phil. Trans.* 1800, vol. xc. p. 255.

[2] *Id. Id.* 1837.

ismatic
ectrum.

imperceptible degrees, and had no definite boundary.[1] In examining the action of all the coloured solid and fluid bodies which he could command, Sir David Brewster was led to observe the action of nitrous acid gas on the spectrum.[2]

ion of
ous acid
on the
trum.

With a fine prism of rock salt, having the largest possible refracting angle, he formed a spectrum with the light of a lamp transmitted through a small thickness of the gas, whose colour was a very pale straw yellow, and he was surprised to observe the spectrum crossed with hundreds of lines or bands, much more distinctly pronounced than those of the solar spectrum. In the violet and blue spaces the lines were sharpest and darkest; they were fainter in the green, and almost imperceptible in the yellow and red spaces. By an increase in the thickness of the gas, the lines were better developed in the yellow and red spaces, and became broader in the blue and violet, a general absorption or extinction of the light advancing from the violet extremity, while a specific absorption was going on, on each scale of the lines or bands. It was not easy to obtain a sufficient thickness of gas to bring out the lines at the red extremity, but our author found that heat produced the same effect as an increase of thickness, and by greatly heating a tube half an inch wide, and full of gas, he was able to exhibit the lines and bands to the very extremity of the red space.

"The power of heat alone," says our author, "to render a gas which is almost colourless as red as blood, without decomposing it, is in itself a most singular result, and my surprise was greatly increased when I afterwards succeeded in rendering the same pale nitrous acid gas so absolutely black by heat, that not a ray of the brightest summer's sun was capable of penetrating it. In making this experiment the tubes frequently exploded, but by using a mask of mica and thick gloves, and placing the tubes in cylinders of tinned iron, with narrow slits to admit the light, there is little danger of any serious accident."

It is a remarkable fact that the liquified gas in the very same tube, produces none of the fixed lines, and exercises no other action on the spectrum than any ordinary fluid of the same orange colour.

As the points of maximum absorption in coloured bodies were distinctly coincident with some of the principal lines in the solar spectrum, our author suspected that the same might be true with regard to the nitrous gas lines, and he therefore formed the solar and the gaseous spectrum with light passing through the same aperture, so that the lines in the one stood opposite to those in the other, aud their coincidence became a matter of simple observation. He then superimposed the two spectra, when both were formed by solar light, and thus exhibited at once the two series of lines and bands, with all their coincidences and deviations. This phenomenon is one of the most splendid in physical optics.

"The general coincidence," continues our author, "thus cognizable by the eye, requires to be more particularly explained. Though some of the larger lines in the gaseous spectrum coincide with some of the larger ones in the solar spectrum, yet, in many cases, faint and narrow lines in the one coincided with strong and broad lines in the other; and there were some strong gaseous lines, and even broad bands, to which I could discover no counterpart in Fraunhofer's map of the spectrum, which at this stage of my inquiry was the standard to which I appealed. This discrepancy at first embarrassed me, and as I observed it in parts of the spectrum where Fraunhofer had drawn every line which he had seen with his finest instruments, I abandoned all hopes of being able to establish the general principle of their identity. I was therefore obliged either to renounce this principle as one contradicted, or rather not confirmed by observation, or to consider Fraunhofer's delineations as in fault, and to enter upon the Herculean task of making a better map of the spectrum.

Prismatic
Spectrum.

"After a little practice in the observation of the solar spectrum, I discovered most of the lines which I had in vain sought for in Fraunhofer's map, as the counterpart of those in the gaseous spectrum. I saw well marked groups, of which he had only given one of the lines, and shaded bands, and well defined lines, which his method of observation had not permitted him to discover.

New maps
of the solar
spectrum.

"After I had laid down all the principal features in the spectrum, I was able to examine the two classes of lines *pari passu*. The action of the gas upon invisible lines in the spectrum rendered them visible by slightly enlarging them, and this enlargement of a solar line indicated the existence of a corresponding line in the gaseous spectrum.

"By this double process, and by methods of observation which I believe have never before been used in optical researches, I have been able to execute three different maps of the spectrum: *first*, a map of the lines in the solar spectrum; *secondly*, a map of the same spectrum, exhibiting at the same time the action of nitrous acid gas upon solar light, previously deprived of a number of its definite rays; and, *thirdly*, a map shewing the action of the gas upon a continuous and uninterrupted spectrum of artificial white light. The general scale of these delineations is *four* times greater than that of Fraunhofer, but some portions of them are drawn on a scale *twelve* times greater, which became necessary from the impossibility of representing in narrower limits the numerous lines and bands which I have discovered. The length of Fraunhofer's spectrum is $15\frac{1}{2}$ inches; mine, upon the same scale, is nearly 17 inches. The length of the general spectrum, which I have delineated, is about *five* feet eight inches, and the length of a spectrum, corresponding to the scale on which I have delineated parts of it, is *seventeen* feet.

"Fraunhofer has laid down in his map 354 lines, but in the delineations which I have executed, the spectrum is divided into more than 2000 visible and easily recognised portions, separated from each other by lines more or less marked, according as we use the simple solar spectrum, or the solar and gaseous spectra combined, or the gaseous spectrum itself, in which any breadth can be given to the dark spaces."

In this minute examination of the spectrum, our author was led to the discovery of a system of lines and bands, particularly in the red and green spaces, which at other times wholly disappeared; but by a diligent comparison of these observations, he found that these *lines and bands depended on the proximity of the sun to the horizon, and were produced by the absorptive action of the earth's atmosphere.* Sir David Brewster is about to publish his map of the lines of the spectrum, as produced by the light of the sun itself, and another map of the spectrum, as modified by the action of the earth's atmosphere. He has, however, made the following general observations on the subject, in reference to the fixed lines of Fraunhofer:—"The atmosphere," he remarks, "acts very powerfully round the line D, and in the space immediately on the least refrangible side of it. It developes a beautiful line in the middle of the double line D, and by enlarging a group of small lines on the red side of D, it creates a band almost as dark as the triple line D itself. It widens generally all the lines, but especially the darkest one, which I call *m*, between C and D. It developes a band on the least refrangible side of *m*, and it acts especially upon several lines, and developes a separate band

[1] A remarkable example of a very definite action on a part of the spectrum was discovered by Sir D. Brewster in the triple oxalate of chromium and potash. It absorbs a very definite band on the least refrangible side of B, a part of the spectrum over which it exercises no general absorptive action. This band lies in the space B*a* of Fraunhofer's map, so that if x is its place, Bx will be $\frac{1}{3}$ B*a*, or its index of refraction in the water spectrum is almost exactly 1·33070·1 —See *Phil. Trans.* 1835, p. 93.

[2] *Phil. Trans.* 1837, part ii. p. 245.—*Edin. Trans.* vol. xii.

Periodical Colours.

on the most refrangible side of C. The lines A, B, and C are greatly widened, and lines and bands are particularly developed between A and B, and generally throughout all the red space.

"Most of the lines thus widened by the atmosphere are faint lines previously existing in the spectrum, and I have no doubt that they would be seen in the spectrum of the lime ball light condensed by a polyzonal lens, and acted upon by thirty miles of atmosphere.

"The absorptive action of the atmosphere shews itself in a less precise manner in the production of dark bands, whose limits are not distinctly defined. A very remarkable narrow one, corresponding to one produced by the nitrous acid gas, is situated on the most refrangible side of C. Another very broad one lies on the most refrangible side of D, close to a sharp and broad band of yellow light, displayed by the general absorption of the corresponding part of the superimposed blue spectrum. There is also an imperfectly defined atmospheric action, corresponding to a group of lines where Dr. Wollaston placed his line C.

"This general description of the atmospheric lines, while it indicates the remarkable fact, that the same absorptive elements which exist in nitrous acid gas, exist also in the atmospheres of the sun and of the earth, leads us to anticipate very interesting results from the examination of the spectra of the planets. Fraunhofer had observed in the spectra of Venus and Mars some of the principal lines of the solar spectrum. This, indeed, is a necessary consequence of their being illuminated by the sun, for no change which the light of that luminary can undergo is capable of replacing the rays which it has lost. But while we must find in the spectra of the planets and their satellites, all the defective lines in the solar spectrum, we may confidently look for others arising from the double transit of the sun's light through the atmospheres which surround them."

PART V. ON PERIODICAL COLOURS.

Periodical colours.

The phenomena of periodical, or recurrent colours, as Dr. Young has very appropriately called them, are among the most interesting in optics, and have been treated of by him with great ability, under our article on CHROMATICS, though not in that popular and descriptive manner, which is required in a work like this. We shall therefore endeavour to give as perspicuous an account as we can of this interesting portion of physical optics.

SECT. I.—*On the Interference of Light.*

Interference of light

The discovery of the interference of light in its simplest form, is due to Grimaldi, as we have already seen. He admitted the sun's light into a dark room, through two small and equal apertures of a circular form. Two cones of diverging light were thus formed, and by receiving them on a screen, held beyond the place where the cones intersected each other, two overlapping luminous circles were seen on the screen. A partially illuminated penumbra surrounded each of these cones, and at the place where the rays from each aperture met, the screen was, generally speaking, more strongly illuminated by the union of the two lights; but the boundaries of the penumbral portions which overlap are much darker than the corresponding portions of the penumbra which do not overlap, as if the one light had at this part put out the other. Upon intercepting the light from one of the apertures, this dark part became brighter, and upon restoring the light it again became darker. The result, therefore, was here unambiguous, and justified the observation of Grimaldi, "that an illuminated surface may be rendered darker by the addition of light."

Dr. Hooke made a similar experiment, and observed the darkness produced at the overlapping part of the two cones; but this result, remarkable as it was, seems to have excited no interest during nearly a century and a half, till Dr. Young, who was unacquainted with the experiment of Grimaldi, obtained the same result in a different manner, and thus laid the foundation of the most interesting department of physical optics. The following is the experiment which he gave as "*An Experimental Demonstration of the Interference of Light.*"[1] "I made a small hole in a window shutter, and covered it with a piece of thick paper, which I perforated with a fine needle. For greater convenience of observation I placed a small looking-glass without the window shutter in such a position as to reflect the sun's light in a direction nearly horizontal upon the opposite wall, and to cause the cone of diverging light to pass over a table on which were several little screens of card paper. I brought into a sunbeam a slip of card about $\frac{1}{30}$th of an inch in breadth, and observed its shadow either on the wall, or on other cards held at different distances. Beside the fringe of colour on each side of the shadow, the shadow itself was divided by similar parallel fringes of smaller dimensions, differing in number according to the distance at which the shadow was observed, but leaving the middle of the shadow always white. Now these fringes were the joint effects of the portions of light passing on each side of the slip of card, and inflected or rather diffracted into the shadow. For a little screen being placed either before the card, or a few inches behind it, so as either to throw the edge of its shadow on the margin of the card, or to receive on its own margin the extremity of the shadow of the card, all the fringes which had before been observed in the shadow on the wall, immediately disappeared, although the light inflected on the other side was allowed to retain its course, and although this light must have undergone any modification that the proximity of the other edge of the slip of card might have been capable of occasioning. . . . Nor was it for want of a sufficient intensity of light that one of the two portions was incapable of producing the fringes alone; for when they were both uninterrupted the lines appeared, even if the intensity was reduced to one-tenth or one-twentieth."

Periodical Colours. Dr Young's experiment.

Although this experiment is a very decisive one, yet M. Fresnel made one still more instructive and general, and free from any of the objections that might have been urged against that of Dr. Young. He took two plane mirrors M, N, which were inclined at a very great angle, a little less than 180°, and having allowed a beam of light Ra, Rb, proceeding from a luminous point R such us the focus of a small lens, he received the reflected rays on a piece of paper PQ. If the light was homogeneous, there was seen upon the paper a succession of bright and dark bands alternating. These bands are parallel to the line of intersection of the two mirrors, and they are placed symmetrically on both sides of a plane passing through the line of intersection of the mirrors, and through a point A bisecting the distance of the points D, E, the virtual points of divergence of the two reflected pencils aG, bG. That these parallel bands are produced by the mutual interference of the two beams, is at once proved by intercepting one of them, by covering one of the mirrors, when the whole series disappears. It is found also by measuring distances of the same bands from the line of intersection of the mirrors, and when the paper PQ, is placed at different distances from the mirrors, that their different

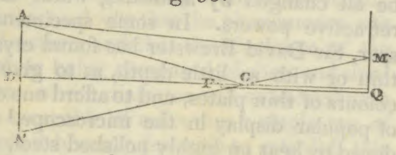
Periodical Colours.

points lie in hyperbolas whose foci are D, E, and common centre A.

Professor Lloyd's experiment.

A still more simple and elegant method of exhibiting the phenomena of interference, has been given by Professor Lloyd of Dublin, which any person may repeat with a single piece of plate glass. Having placed horizontally a piece of black glass QP, with his eye behind it at QM, he viewed by very oblique reflexion, when

Fig. 93.



the angle of incidence was nearly 90°, a horizontal narrow aperture placed at A, a distance of three feet from the reflector QP. The proper degree of obliquity was easily found by bringing the reflected image of the aperture A to coincide very nearly with the direct image, in which case the direction of the reflected plane BPQ, bisected the distance AA′. When the ray AM, which fell directly upon the eye at M, interfered with the reflected rays CM, which reached it by a longer path, they produced a system of fringes or bands, which were distinctly visible when received upon an eye-piece placed at a short distance from the reflector. This system of bands was exactly similar to one-half of the system seen in Fresnel's experiment. With compound white light the first band was a *bright* one and *colourless*. This was followed by a very sharply defined black band; then came a coloured, and so on alternately, seven alternations being easily counted, and the breadth of the bands being, as near as the eye could judge, the same throughout the series, and increasing with the obliquity of the reflected beam. "The first dark band was of *intense blackness*, but the darkness of the succeeding bands were less intense, as they were of higher orders, and after three or four orders they were completely obliterated by the closing in of the bright bands. At the same time the coloration of the bright bands increased with the order of the band, until after six or seven alternations, the colours of different orders became superimposed, and the bands were thus lost in a diffused light of nearly uniform intensity."[1] "These bands," continues Professor Lloyd, "are most perfectly defined when the eye-piece is close to the reflector. Their breadth and coloration increased with the distance of the eye-piece, but remained of a finite and very sensible magnitude, when the latter was brought into actual contact with the edge, a circumstance which distinguished them altogether from the diffracted fringes formed on the boundary of the shadow."

When homogeneous light is used, the bands are alternately bright and dark, and varying in magnitude with the refrangibility of the light, as will be afterwards more fully explained. If the light of the sun is used, the bands may be distinctly seen upon a white screen placed at MQ. That they are produced by interference may be easily proved, either by stopping the direct ray AM, or the reflected ones CM, when the whole system of bands disappears.

The leading phenomena of interference may be likewise exhibited by transmitting the light emanating from a luminous point through the two faces of a prism, the inclination of which is about 180°. The pencil or ray passing through one of the faces, will be slightly inclined to the ray passing through the other, at a small angle, and will interfere with it at their point of concourse, and produce the usual fringes. This form of the experiment is described by Sir Isaac Newton, who considered the fringes as produced by inflexion.

In all the preceding experiments two pencils of light issuing from the same point or luminous origin, are made again to meet, the one having arrived at the point of concourse by a different and a longer path. Now it is obvious from the experiments, that when the two portions of light thus intervening reach the spot where they interfere by paths exactly equal, they form a bright fringe, having the intensity of its light greater than that of either portion. It is also evident that other bright fringes are produced, when their paths differ in length; and if we suppose d to be the difference of paths by which the second bright fringe is produced, similar bright fringes will be produced when the differences in the lengths of the paths are $2d$, $3d$, $4d$, $5d$, $6d$, &c. But it is manifest from the preceding experiments, that if the two portions of light interfere at intermediate points, or when the difference in the length of their paths is $\frac{1}{2}d$; $d+\frac{1}{2}d$; $2d+\frac{1}{2}d$; $3d+\frac{1}{2}d$; $4d+\frac{1}{2}d$, &c. the two interfering portions *destroy each other* and produce blackness, as appears from the dark fringes lying between the bright ones. Here, then, we have a remarkable property of light established by direct experiment, and well fitted to guide us in our inquiries into the physical cause of the various phenomena of light. We shall find the same beautiful property shewing itself under various aspects in a succession of interesting phenomena, which we shall now proceed to describe.

Sect. II.—*On the Colours of Thin Plates.*

Colours of thin plates.

The colours of thin plates were first observed by Mr. Boyle, who remarks that all chemical essential oils, as also good spirits of wine, by shaking till they rise in bubbles, appear of various colours, which immediately vanish when the bubles burst, so that a colourless liquor may be immediately made to exhibit a variety of colours, and lose them in a moment, without any change in its essential principles. Mr. Boyle also noticed these colours in soap bubbles and in turpentine, and he succeeded in blowing glass sufficiently thin to exhibit them. In 1666 Lord Brereton observed similar colours produced by the thin plates which are formed on the surface of glass by the action of the weather. In the year 1672 Dr. Hooke exhibited to the Royal Society a soap bubble with all its colours, in fulfilment of a promise which he had made at a previous meeting, "to exhibit something which had neither refraction nor reflexion, and yet was diaphanous." "By means of a glass pipe he blew several small bubbles out of a mixture of soap and water, when it was observable that at first they appeared white and clear, but that after some time the film growing thinner, there appeared upon it all the colours of the rainbow, first a pale yellow, then orange, red, purple, blue, green, with the same series of colours repeated." Dr. Hooke made considerable progress in the investigation of this class of phenomena, and made experiments with thin plates of Muscovy glass, (Mica). He found that a faint yellow plate of this substance laid upon a blue one constituted a very dark purple; and Sir Isaac Newton, in a private letter to Dr. Hooke, a copy of which is now before us,[2] acknowledges that Hooke had observed previous to him, "the dilatation of the coloured rings by the obliquation of the eye, and the apparition of a black spot at the contact of two convex lenses, and at the top of a water bubble."

Boyle.

Hooke.

Newton.

Sir Isaac Newton, whose investigations we shall presently give in his own words, made great progress in discovering the law of the phenomena, and it is a curious fact not to be overlooked by physical inquirers, that his theory of the phenomena, elaborated with the utmost care and generalising an extensive series of facts, is now exploded, while the theoretical views of Dr. Hooke are almost universally admitted.

Mr. Melville of Edinburgh proposed to make a permanent soap bubble by freezing, but we believe the experiment

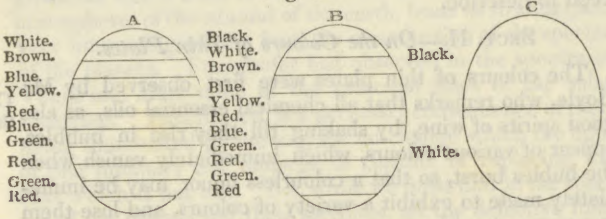
[1] *Transactions of the Royal Irish Academy*, vol. xvii.

[2] Dated Cambridge, February 5, 1675-6.

Dr Reade's permanent soap bubble.

has never yet succeeded. Dr. Joseph Reade has however been more fortunate in making what may be called a permanent soap bubble, for illustrating the colours of thin plates, which we saw him exhibit at the meeting of the Physical Section of the British Association at Liverpool in 1837. The following is his own account of the method of making it: "Having put two ounces of distilled water into an eight-ounce phial, and having added about the size of a large pea of Castile soap, I placed the bottle in a saucepan of boiling water on the fire; the bottle was speedily filled with a dense volume of vapour, which expelled all the air. I now corked it, and after cooling and thus condensing the vapour, had perhaps as perfect a vacuum as could be formed, even by the best air-pump. I now held the bottle laterally between my hands, and by means of a circular and brisk motion formed a circular film, on which by resting the bottle on an inclined plane, were formed after a short time, all the parallel bands or series of colours in the following order: 1. a white or silvery segment at top; 2. a snuff-coloured brown, inclined at bottom to a deep red; 3. blue; 4. yellow; 5. red; 6. blue; 7. green; 8. red; 9. green; 10. red; 11. green. (As in fig. A.)

Fig. 94.



"After some time a black segment was seen to form at the top of the white, and continually to increase in size. (See fig. B.) After a few minutes the parallel bands increased in breadth, and running into one another, only three or four distinct bands were seen. Nothing can exceed the beauty of these colours, equal to those of the rainbow, or the plumage of the tropics: whilst writing this description, I have these bands in a bottle before me, feasting my eyes on their beauty. In a few minutes more this black segment or aqueous film occupies, perhaps, half the circular film, and the lower half becomes white tinged with orange. (See fig. C.)

"If we now incline the bottle towards the experimenter's breast, the saponaceous atoms producing these colours, are seen to float in the region of the black or aqueous; when placed again on the inclined plane, they fall to the bottom of the film. In some time more the entire film becomes black, and all the colours disappear.

"Having now placed the bottle in a basin of boiling water, the evaporation was increased, and the black film soon became clothed with saponaceous atoms, which being variously condensed, produced all the colours of the clouds when the sun is setting on a summer's evening. On again placing the bottle on the inclined plane, the parallel bands were again formed by the attraction of cohesion, and the colours afterwards gave place to the black film. I held the bottle laterally between my hands, and by means of a circular motion washed it, and thus clothed it with saponaceous atoms, which went through the same process on placing the bottle on the inclined plane. By means of washing the film every morning, I preserved it for more than three weeks."

Colours of thin plates exhibited in nature.

The colours of thin plates are often exhibited in nature in the most beautiful manner. On the surface of little pools of mossy water, and especially in the proximity of springs containing iron, we observe thin bright films generally whitish and often yellow and reddish. Between the plates of a mass of mica, and sulphate of lime, and talc, we observe thousands of open spaces where the rings are sometimes circular, consisting only of the first tint above blackness, viz., the white of the first order, sometimes two, three, or more colours according to their size, while at other times the rings or fringes are extremely numerous and often irregular. These colours are all produced by thin plates of air or of vacuity in these fissile minerals, and the colours may be all changed by admitting water or fluids of different refractive powers. In some specimens of Labrador felspar, Sir David Brewster has found crystallised cavities so thin or with so little depth, as to give the most splendid colours of thin plates, and to afford one of the finest subjects of popular display in the microscope.[1] The colours produced by heat on highly polished steel, are all the colours of a thin plate of oxide; and they are often beautifully displayed on the sides and on the bars of grates.

When glass is exposed to the action of the weather, its surface acquires a thin film, which at first can only be rendered visible by examining the faint light reflected from it when it is in contact with a fluid of nearly the same refractive power. It forms most rapidly on the panes of glass in stable windows, but it is seen in the highest perfection in the specimens of decomposed glass found among the remains of Roman buildings. The glass is to a certain depth entirely decomposed into thin films of extreme beauty, reflecting the most brilliant colours to the eye, and transmitting tints of the most exquisite brilliancy, and far surpassing any of the colours produced by art.[2] Coloured films of the richest tints are also seen upon both the faces of cleavage of a sort of artificial mother of pearl, which has been called *nacrite*, and described by Mr. Horner in the *Phil. Trans.*[3] These films are all thin plates of extreme tenuity.

When we breathe upon glass at a proper temperature, and examine with a magnifier the margin of the film while evaporating, or when we observe the evaporation of different volatile fluids, we shall perceive many interesting examples of the colour of thin plates.

One of the finest exhibitions of this kind with which we are acquainted, is that which is produced by the ammonio-sulphate of copper, and which was observed by Sir David Brewster. A solution of the ammonio-sulphate of copper in water, is spread upon a clear plate of glass or any other surface. In the course of an hour or two, a similarly coloured film is formed upon its surface, exhibiting the colours of thin plates from the white of the first order upwards. When the solution is strong, or the stratum of fluid deep, the thickness of the film increases, and the colours rise to higher orders, of a beautiful green and pink colour. When the colours are such as we would wish to preserve, an aperture must be made in the film, and by inclining the plate the fluid must be allowed to run out slowly, leaving the film on the surface of the glass. This film will become hard and permanent after the aqueous part of it has been evaporated. The fringes of colour take the shape of the mass of fluid, or of the piece of glass whose surface is covered with it.

One of the most extraordinary examples of the colours of thin plates, or rather of the blackness that immediately precedes these colours, and one which almost requires the evidence of ocular demonstration to credit, is the existence of filaments, or of a down of quartz so exceedingly minute as to be incapable of reflecting light. The very remarkable specimen of quartz in which this was discovered by Sir David Brewster belongs to the cabinet of the Duchess of Gordon. The original crystal was $2\frac{1}{4}$ inches in diameter, and of a light smoky colour, but impervious to light except in small pieces. Mr. Sanderson, lapidary in Edinburgh, had broken up the crystal for the purposes of his profession, but the apparent foulness of the fracture induced him to lay it aside. The following is an account given by Sir David Brewster, of the principal fracture.

[1] *Edin. Trans.* vol. xi. p. 322. [2] *Phil. Trans.* 1837, part ii. [3] Id. Id. 1836, p. 49, and 1837, part ii.

Periodical Colours.

"At first sight, the absolute blackness of the separated surfaces seemed to me as it did to every one, to be owing to a thin film of opaque and minutely divided matter that had insinuated itself into a fissure of the crystal; but this opinion was immediately overturned when I observed that both surfaces were equally and uniformly black, and that they were also perfectly transparent by transmitted light.

"Although I had now no doubt that the phenomenon was entirely of an optical nature, and that the blackness of the surfaces arose from their being composed of short and slender filaments of quartz, whose diameter was so exceedingly small that they were incapable of reflecting a single ray of the strongest light, yet it became desirable to establish this curious fact by experimental evidence.

"Having found that no detergent substances either removed or diminished the superficial blackness, I subjected the fragment to the action of cold and hot acids; but the surface continued unaltered by these operations. I now immersed the fragment in oil of anise seed, which approaches to quartz in its refractive power, and upon examining the light reflected at the separating surfaces of the oil and the quartz, I found that the blackness disappeared, and that the fragment, whether seen by reflected or transmitted light, comported itself like any other piece of quartz of the same translucency. Upon removing the oil from the surfaces, it resumed its original blackness, and the filamentous or velvety nature of the surface was rendered evident to the eye by the slight change of tint which was produced by pressing the filaments to one side.

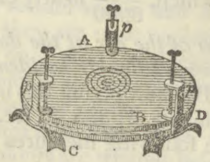
"As the preceding experiments are sufficient to prove that the size of the minute filaments was less than the thickness of a thin plate of quartz which lost the power of reflecting light, it became interesting to obtain an approximate measure of their magnitude. The thinnest substance ever observed, is the aqueous films of the soap bubble previous to its bursting. Newton, however, remarked that the films still reflected a faint image of the candle or of the sun. Hence its thickness must have corresponded nearly with what Newton calls the *beginning of black*, which appears in water at a thickness of the 750,000th part of an inch. The tint, however, of the quartz surface is of a much deeper character, and cannot exceed the *very black* of Newton's scale which corresponds in *quartz* to *one-third of the one-millionth part of an inch*, or to *one-fourth* of the thinnest part of the soap bubble.

"If the two surfaces of quartz had separated by filaments of a larger size, the colour of the filamentous surface might have been *red*, or *blue*, or *yellow*, or *green*; but though such a structure would have been more dazzling to the eye, it yet would have been less wonderful than the one which has now been described."

The colours of thin plates may also be exhibited by pressing together two glass prisms that have moderate refracting angles. Various coloured fringes or portions of coloured rings will be seen by viewing the light reflected from the surfaces in contact, and in a much fainter degree, by examining the transmitted light. The same phenomena may be seen with unusual brilliancy, by taking a thick piece of glass, and having made a scratch on one side of it with a file, apply a heated wire to the scratch, so as to produce a crack in the glass, which may be extended at pleasure by a second and third application of the hot wire. If we now examine the surface of this crack in different directions, we shall see it covered with coloured fringes, which may be made to vary in breadth and position, by opening or closing the crack with the force of the hand.

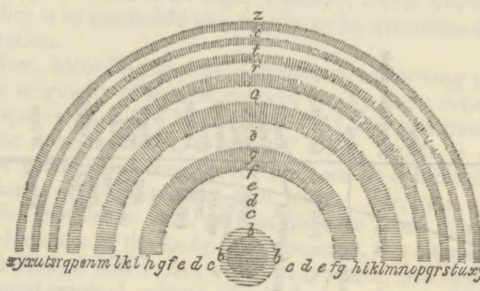
When we wish to examine and measure the coloured rings with care, the method used first by Hooke, and subsequently by Newton, should be adopted. Two convex lenses of very long focal length are placed the one above the other, so as to touch at their vertex; or a plano-convex lens may have its plane side AB laid upon the convex side CD, fig. 97, of another lens. Sir Isaac Newton used for the uppermost lens a plano-convex one, whose focal length was fourteen feet, and for the lowermost a double convex lens, whose focal length was fifty feet. These lenses must then be held together, and pressed if necessary by three clamp screws, as shewn in fig. 95. The following is the general account of the phenomenon given by Sir Isaac Newton, though somewhat abridged:—

Fig. 95.



"Next to the pellucid central spot made by the contact of the glasses, succeeded *blue*, *white*, *yellow*, and *red*. The blue was so little in quantity, that I could not distinguish any violet in it, but the *yellow* and *red* were as copious as the *white*, though four or five times more than the *blue*. The next order of colours round those in the *second*, was *violet*, *blue*, *green*, *yellow*, and *red*, all of them copious and vivid except the green. The *third* order was *purple*, *blue*, *green*, *yellow*, and *red*, the green being more vivid than in the last order. The *fourth* order was only *green* and *red*, the green being copious and lively, being bluish on one side, and yellowish on the other. The red was very imperfect: the succeeding rings or orders of colours were very faint; and after three or four orders, they ended in perfect whiteness. The form of the whole system of rings, when the lenses were most compressed, so as to produce the black spot in the centre, as shewn in fig. 96, where *a, b, c, d, e; f, g, h, i, k;*

Fig. 96.



l, m, n, o, p; q, r; s, t; v, x; y, z, indicate the different colours beginning at the centre, viz. 1. *black, blue, white, yellow, red*; 2. *violet, blue, green, yellow, red*; 3. *purple, blue, green, yellow, red*; 4. *green, red*; 5. *greenish blue, red*; 6. *greenish blue, pale red*; 7. *greenish blue, reddish white*.

In order to find the interval between the glasses, or the thickness of the plate of included air (or space) at which each colour was produced, Sir Isaac measured the diameter of the first six rings at their brightest part, and found their squares to be in the arithmetical progression of the odd numbers 1, 3, 5, 7, 9, &c., and the intervals between the glasses are obviously in the same progression, one of the surfaces being plane, and the other spherical. He then measured the diameter of the rings at their darkest points, and found their squares to be in the arithmetical progression of the even numbers, 2, 4, 6, 8, 10, &c.

In order to find the absolute thickness of the plate of air or space at which these different rings were produced, he measured the diameter of the fifth ring at its darkest point as produced by the different object-glasses.

Diameter of Sphericity of the object-glass.	Diameter of fifth dark ring.
182 inches	$\frac{100}{1774784}$
184 inches	$\frac{5}{88850}$

and dividing these diameters by 5, we obtain the diameter

Periodical Colours.

of the first ring he obtained, $\frac{1}{88739}$ and $\frac{1}{88850}$; but as these measurements were taken at an angle of incidence of 4°, the results must be diminished in the ratio of the seccant of 4°, or 10029, so that we have $\frac{1}{88952}$ and $\frac{1}{89063}$, the mean of which, $\frac{1}{8900}$ nearly expresses in parts of an inch, *the thickness of the air at the darkest part of the first dark ring at a perpendicular incidence.*

By multiplying this interval by the series of odd and even numbers, 1, 3, 5, 7, &c., and 2, 4, 6, and 8, &c., we obtain the following measures of all the rings:—

	Thickness of the air at the brightest part.	Thickness of the air at the darkest part.
First Ring,	$\frac{1}{178000}$	$\frac{2}{178000}$ or $\frac{1}{89000}$
Second Ring,	$\frac{3}{178000}$	$\frac{4}{17800}$ $\frac{2}{89000}$
Third Ring,	$\frac{5}{178000}$	$\frac{6}{17800}$ $\frac{3}{89000}$
Fourth Ring,	$\frac{7}{17800}$	$\frac{8}{17800}$ $\frac{4}{89000}$

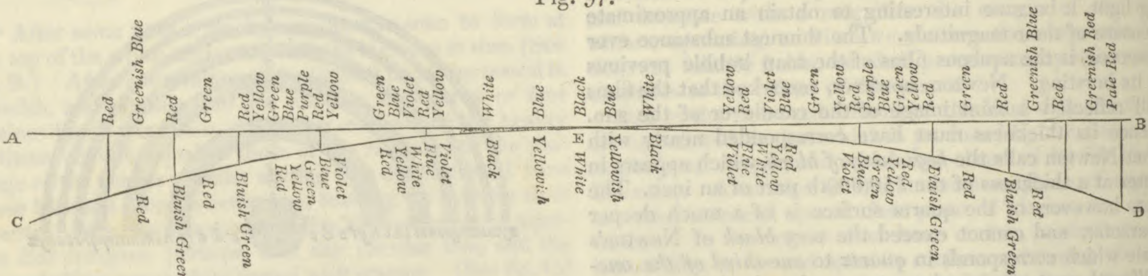
Effects of oblique incidence.

After measuring the diameters of the rings at different angles of incidence, Sir Isaac obtained the following results:

Angle of Incidence on the Air.		Angle of Refraction into the Air.		Diameter of the Ring.	Thickness of the Air.
Degr.	Min.				
00	00	00	00	10	10
06	26	10	00	$10\frac{1}{13}$	$10\frac{2}{13}$
12	45	20	00	$10\frac{1}{3}$	$10\frac{2}{3}$
18	49	30	00	$10\frac{3}{4}$	$11\frac{1}{2}$
24	30	40	00	$11\frac{2}{5}$	13
29	37	50	00	$12\frac{1}{2}$	$15\frac{1}{2}$
33	58	60	00	14	20
35	47	65	00	$15\frac{1}{4}$	$23\frac{1}{4}$
37	19	70	00	$16\frac{1}{5}$	$28\frac{1}{4}$
38	33	75	00	$19\frac{1}{4}$	37
39	27	80	00	$22\frac{6}{9}$	$52\frac{1}{4}$
40	00	85	00	29	$84\frac{1}{13}$
40	11	90	00	35	$122\frac{1}{2}$

From the results given in the preceding table, Sir Isaac Newton has deduced the following rule:—"That the thickness of the air is proportional to the secant of an angle, whose sine is a certain mean proportional between the sines of incidence and refraction; and that mean proportional, so far as, by these measures, I can determine it, is the first of an 106 arithmetical mean proportionals between these sines counted from the higher sine, that is, from the sine of refraction when the refraction is made out of the glass into the plate of air, or from the sine of ineidence when the refraction is made out of the plate of air into the glass."

Fig. 97.



Sir Isaac next proceeds to describe the rings formed by the light transmitted through the two glasses. In this system of transmitted rings, the order of the colours was *yellowish red; black, violet, blue, white, yellow, red; violet, blue, green, yellow, red.* The colours in these rings are very faint at a perpendicular incidence, but become brighter as the incidence increases.

In fig. 97 Sir Isaac has represented the different colours reflected and transmitted, AB and CD being the surfaces of the glasses which touch at E, and the lines uniting them representing their distances in arithmetical progression. The words above the straight line AB are the colours of the *reflected* rings, and those below the circular arch CD those of the transmitted rings.

When water was introduced between the lenses, the colours became fainter, and the rings less, and Sir Isaac found that the intervals were inversely as the indices of refraction in water and air.

The rings were always larger in the homogeneous *red* light of the spectrum than in the *violet* light, in the ratio of $14\frac{1}{2}$ to 9, and he concluded from more detailed observations that the thicknesses of the air between the glasses when the rays were successively formed by the limits of the seven different colours, *red, orange, yellow, green, blue, indigo,* and *violet*, are to one another as the cube roots of the squares of the eight lengths of a cord which sound the notes in an eighth, *sol, la, fa, sol, la, mi, fa, sol,* that is, in the cube roots of the squares of the numbers 1, $\frac{8}{9}$, $\frac{5}{6}$, $\frac{3}{4}$, $\frac{2}{3}$, $\frac{3}{5}$, $\frac{9}{16}$, $\frac{1}{2}$, or 1; 0·924; 0·885; 0·825; 0·763; 0·711; 0·681; 0·630, that is, if 1 be the interior diameter of any such red ring formed by the extreme red rays, the cube root of $\frac{8}{9}$ will be the interior diameter of a ring at the boundary of the red and orange, and so on.[1]

The colours of thin plates of fluid or solid bodies are not so easily studied as those of air, from the difficulty of procuring, and working with, such evanescent films. Sir Isaac Newton, however, studied them in soap bubbles which, as soon as they were blown, he covered with a clear glass. In this way he observed the colours to emerge like so many concentric rings surrounding the summit of the bubble. As the bubble became thinner, and the subsidence and evaporation of the water, the rings dilated slowly, till they covered the whole bubble, descending in order to the bottom of it, till where they vanished successively. After all the colours were emerged at the top, there grew in the centre of the rings a small round black spot, which continually dilated itself till it became sometimes more than a-half or three quarters of an inch in breadth before the bubble broke. Some light was still reflected from the water at this spot, and Sir Isaac saw within it several smaller round spots much blacker and

[1] It has been noticed by M. Le Blanc, that if the two extreme terms of the preceding numbers, or any other two equidistant from th extremes be multiplied together, their product will always be equal to $\frac{1}{2}$

eriodical Colours.

darker than the rest, but still capable, like the larger one, of reflecting faintly an image of the sun.

By observing how much the colours at the same places of the bubble, or at divers places of equal thicknesses, were varied by the several obliquities of the rings, Sir Isaac obtained the following thicknesses of the water requisite to exhibit one and the same colour at several obliquities :—

Incidence on the water.	Refraction into the water.	Thickness of the water.
0°	0° 0′	10
15	11 11	$10\frac{1}{4}$
30	22 1	$10\frac{4}{5}$
45	32 2	$11\frac{4}{5}$
60	40 30	13
75	46 25	$14\frac{1}{2}$
90	48 35	$15\frac{1}{5}$

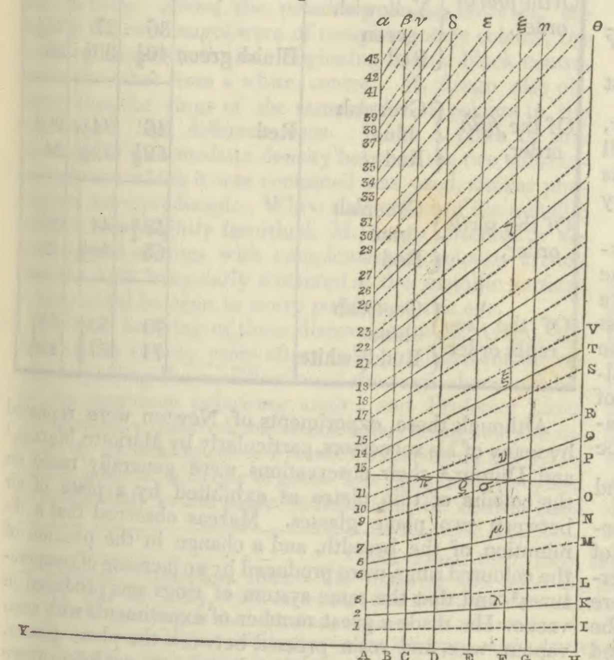
These results harmonise entirely with the rule already given for thin plates of air.

When the system of rings seen by reflection was examined by a prism, and perhaps only eight rings visible, Sir Isaac counted sometimes more than forty on the side of the system to which the refraction was made, though he reckoned by estimation more than a hundred. Soap bubbles also, before they exhibited any colours to the naked eye, have appeared through a prism girded about with many parallel and horizontal rings, to produce which effect it was necessary to hold the prism parallel, or very nearly parallel to the horizon, and to dispose it so that the rings might be refracted upwards.

mposi- of the urs of plates.

Sir Isaac then proceeds to a very important part of the subject, namely, to explain the composition of the colours of thin plates, a topic of great interest and extensive application : "Let there be taken," says he, "on any right line from the point Y, fig. 98, the lengths YA, YB, YC, YD,

Fig. 98.



&c. in the proportion of the numbers, 6300, 6814, 7114, 8255, 8855, 9243, 1000 ; and at the points A, B, C, D, E, F, G, &c. let perpendiculars Aα, Bβ, Cγ, &c. be erected by whose intervals the extent of the several colours set underneath against them is to be represented. Then divide the line Aα in such proportions as the Nos. 1, 2, 3, 5, 7, 9, &c. set at the points of division denote, and through these divisions from Y draw lines 1 L, 2 K, 3 L, 5 M, 6 N.

Periodical Colours.

Now, if A2 be supposed to represent the thickness of any thin transparent body, of which the internal violet is most copiously reflected on the first ring, then HK will represent its thickness, at which the outermost red is most copiously reflected in the same series. Also A 6 and HN will denote the thicknesses at which those extreme colours are most copiously reflected in the second series, and A 10 and HQ the thicknesses at which they are most copiously reflected in the third series, and so on. And the thickness at which any of the intermediate colours are reflected most copiously, will be defined by the distance of the line AH from the intermediate parts of the lines 2 K, 6 N, 10 Q, &c. against which the names of those colours are written below.

But, farther, to define the latitude of these colours in each ring or series, let A 1 be the least thickness and A 3 the greatest thickness, at which the extreme violet in the first series is reflected, and let HI, and HL, be the like limits for the extreme red, and let the intermediate colours be limited by the intermediate parts of the lines 1 I, 3 L, against which the names of those colours are written, and so on. But yet with this caution, that the reflections be supposed strongest at the intermediate spaces, 2 K, 6 N, 10 Q, &c. and from thence to decrease gradually towards these limits, 1 I, 3 L, 5 M, 7 O, &c. on either side ; where you must not conceive them to be precisely limited, but to decay indefinitely. And whereas I have assigned the same latitude to every series ; I did it, because although the colours in the first series seem to be a little broader than the rest, by reason of a stronger reflexion there, yet that inequality is so insensible as scarcely to be determined by observation.

Now, according to this description, conceiving that the rays, originally of several colours, are by turns reflected at the spaces 1 I L 3, 5 M O 7, 9 P R 11, &c. and transmitted at the spaces AHI 1, 3 LM 5, 7 OP 9, &c. it is easy to know what colour must in the open air be exhibited at any thickness of a transparent thin body. For, if a ruler be applied parallel to AH, at that distance from it by which the thickness of the body is represented, the alternate spaces 1 IL 3, 5 MO 7, &c. which it crosseth, will denote the reflected original colours, of which the colour exhibited in the open air is compounded. Thus, if the constitution of the green in the third series of colours be desired, apply the ruler as you see at $\pi\ \rho\ \sigma\ \phi$, and by its passing through some of the blue at π, and yellow at σ, as well as through the green at ρ, you may conclude that the green exhibited at that thickness of the body is principally consituted of original green, but not without a mixture of some blue and yellow.

By this means you may know how the colours from the centre of the outward rings ought to succeed in order as they were described. For, if you move the ruler gradually from AH through all distances, having passed over the first space which denotes little or no reflexion to be made by the thinnest substances, it will first arrive at 1 the violet, and then very quickly at the blue and green, which, together with that violet compound blue, and then at the yellow and red, by whose farther addition that blue is converted into whiteness, which whiteness continues during the transit of the edge of the ruler from I to 3, and after that by the successive deficiency of its component colours, turns first to compound yellow, and then to red, and last of all the red ceaseth at L. Then begin the colours of the second series, which succeed in order during the transit of the edge of the ruler from 5 to O, and are more lively than before, because more expanded and severed. And for the same reason, instead of the former white there intercedes between the blue and yellow a mixture of orange, yellow, green, blue, and indigo, all which together ought

Periodical Colours.

to exhibit a dilute and imperfect green. So the colours of the third series all succeed in order; first, the violet, which a little interferes with the red of the second order, and is thereby inclined to a reddish purple; then the blue and green, which are less mixed with other colours, and consequently more lively than before, especially the green: Then follows the yellow, some of which towards the green is distinct and good, but that part of it towards the succeeding red, as also that red, is mixed with the violet and blue of the fourth series, whereby various degrees of red, very much inclining to purple, are compounded. This violet and blue, which should succeed this red, being mixed with, and hidden in it, there succeeds a green. And this at first is much inclined to blue, but soon becomes a good green, the only unmixed and lively colour in this fourth series. For as it verges towards the yellow, it begins to interfere with the colours of the fifth series, by whose mixture the succeeding yellow and red are very much diluted and made dirty, especially the yellow, which, being the weaker colour, is scarce able to shew itself. After this the several series interfere more and more, and their colours become more and more intermixed, till, after three or four more revolutions, (in which the red and blue predominate by turns) all sorts of colours are in all places pretty equally blended, and compound an even whiteness.

And since the rays endued with one colour are transmitted, where those of another colour are reflected, the reason of the colours made by the transmitted light is from hence evident.

If not only the order and species of these colours, but also the precise thickness of the plate, or thin body at which they are exhibited, be desired in parts of an inch, that may be also obtained by the assistance of the preceding observations. For according to these observations, the thickness of the thinned air, which between two glasses exhibited the most luminous parts of the first six rings were $\frac{1}{178000}$, $\frac{3}{178000}$, $\frac{5}{178000}$, $\frac{7}{178000}$, $\frac{9}{178000}$, $\frac{11}{178000}$ parts of an inch. Suppose the light reflected most copiously at these thicknesses be the bright citrine yellow, or confine of yellow and orange, and these thicknesses will be F λ, F μ, F ξ, F o, F τ. And this being known, it is easy to determine what thickness of air is represented by G ϕ, or by any other distance of the ruler from AH.

But farther, since the thickness of air was to the thickness of water, which between the same glasses exhibited the same colour, as 4 to 3, and the colours of thin bodies are not varied by varying the ambient medium; the thickness of a bubble of water, exhibiting any colour, will be $\frac{3}{4}$ of the thickness of air producing the same colour. And so according to the same observations, the thickness of a plate of glass, whose refraction of the mean refrangible ray, is measured by the proportion of the sines 31 to 20, may be $\frac{20}{31}$ of the thickness of air producing the same colours; and the like of other mediums. I do not affirm that this proportion of 20 to 31 holds in all the rays; for the sines of other sorts of rays have other proportions. But the differences of these proportions are so little that I do not here consider them. On these grounds I have composed the following table, wherein the thickness of air, water, and glass, at which each colour is most intense and specific, is expressed in parts of an inch divided into ten hundred thousand equal parts.

The Thickness of Coloured Plates and Particles of Air, Water, and Glass.

	Reflected Tints.	Transmitted Tints.	Air.	Water.	Glass.
Their colours of the *first* order.	Very black		$\frac{1}{2}$	$\frac{3}{8}$	$\frac{10}{31}$
	Black	White	1	$\frac{3}{4}$	$\frac{20}{31}$
	Beginning of black		2	$1\frac{1}{2}$	$1\frac{2}{7}$
	Blue	Yellowish red	$2\frac{2}{5}$	$1\frac{4}{5}$	$1\frac{11}{20}$
	White	Black	$5\frac{1}{4}$	$3\frac{7}{8}$	$3\frac{2}{5}$
	Yellow	Violet	$7\frac{1}{2}$	$5\frac{1}{3}$	$4\frac{3}{5}$
	Orange		8	6	$5\frac{1}{6}$
	Red	Blue	9	$6\frac{3}{4}$	$5\frac{4}{5}$
Of the *second* order,	Violet	White	$11\frac{1}{6}$	$3\frac{3}{8}$	$7\frac{1}{5}$
	Indigo		$12\frac{5}{6}$	$9\frac{5}{8}$	$8\frac{2}{11}$
	Blue	Yellow	14	$10\frac{1}{2}$	9
	Green	Red	$15\frac{1}{8}$	$11\frac{1}{3}$	$9\frac{5}{7}$
	Yellow	Violet	$16\frac{2}{7}$	$12\frac{1}{5}$	$10\frac{2}{5}$
	Orange		$17\frac{2}{9}$	13	$11\frac{1}{9}$
	Bright red	Blue	$18\frac{1}{5}$	$13\frac{3}{4}$	$11\frac{5}{6}$
	Scarlet		$19\frac{2}{3}$	$14\frac{3}{4}$	$12\frac{2}{3}$
Of the third order,	Purple	Green	21	$15\frac{3}{4}$	$13\frac{11}{20}$
	Indigo		$22\frac{1}{40}$	$16\frac{4}{7}$	$14\frac{1}{4}$
	Blue	Yellow	$23\frac{2}{5}$	$17\frac{11}{20}$	$15\frac{1}{10}$
	Green	Red	$25\frac{1}{6}$	$18\frac{6}{10}$	$16\frac{1}{4}$
	Yellow		$27\frac{1}{7}$	$30\frac{1}{3}$	$17\frac{1}{2}$
	Red	Bluish green	29	$21\frac{3}{4}$	$18\frac{5}{7}$
	Bluish red		32	24	$20\frac{2}{3}$
Of the *fourth* order,	Bluish green		24	$25\frac{1}{2}$	22
	Green	Red	$35\frac{2}{7}$	$26\frac{1}{2}$	$22\frac{3}{4}$
	Yellowish green		36	27	$23\frac{2}{9}$
	Red	Bluish green	$40\frac{1}{3}$	$30\frac{1}{4}$	26
Of the *fifth* order,	Greenish blue	Red	46	$34\frac{1}{2}$	$29\frac{2}{3}$
	Red		$52\frac{1}{2}$	$39\frac{3}{8}$	34
Of the *sixth* order,	Greenish blue		$58\frac{3}{4}$	44	38
	Red		65	$48\frac{3}{4}$	42
Of the *seventh* order	Greenish blue		71	$53\frac{1}{4}$	$45\frac{4}{5}$
	Ruddy white		71	$57\frac{3}{4}$	$49\frac{2}{3}$

Although these experiments of Newton were repeated by many of his successors, particularly by Mariotte, Mazeas,[1] and Dutour,[2] their observations were generally made on the colours of thin plates as exhibited by a plate of air between two plane glasses. Mazeas observed that a diminution of the breadth, and a change in the position of the coloured rings, were produced by an increase of temperature;[3] and that the same system of rings was produced in vacuo. He made a great number of experiments with suet, vapour, wax, and rosin pressed between the plane glasses, but he was perplexed with the phenomena, not being aware that he was actually making experiments with mixed plates in which the colours follow an entirely different law. M.

[1] *Mem. Acad. Berlin*, 1752, *and Memoires Presentées*, tom. ii. p. 28.
[2] *Memoires Presentées*, tom. iv. p. 724.
[3] He made the lenses almost red hot, and by pressing them with a rod of iron, he saw the rings produced as before.

Periodical Colours.

Dutour and Sir William Herschel observed the reflected and the transmitted tints at the same time, the last series being reflected to the eye by the lower surface of the glass, and M. Dutour observed these reflected ones more distinctly by making the shadow of an opaque body pass over the upper surface. Sir W. Herschel observed additional sets of rings by increasing the number of reflecting faces; and in producing the primary reflected system by a lens pressed against a metallic reflector, he remarks that the transmitted system must in this case be conceived to have been absorbed by the metallic surface.[1]

Arago.

In an interesting paper on the colours of thin plates published in the *Mémoires D'Arcueil*,[2] M. Arago has given an account of some important discoveries on this subject. In viewing the reflected rings through a rhomb of Iceland spar, having its principal section parallel or perpendicular to the plane of incidence, he observed, that the intensity of light in one of the images, varied with the angle of incidence, and that this image vanished at an incidence of 35° the maximum polarising angle for glass. He discovered the very same property in the transmitted rings. This eminent philosopher has also shewn, that when the reflected and the transmitted systems of rings are superposed, they completely neutralise each other, forming white light; and hence he concluded, that their colours were complementary, and the intensities of their illumination exactly the same.

M. Arago next examined the system of rings when formed between a lens and a metallic reflector. When he observed them with the rhomb of spar above mentioned, one of the images vanished as formerly at 35° of incidence, the *angle of maximum polarisation of glass;* but *above* and *below* that angle M. Arago observed the most singular phenomena. At incidences *below* 35°, the two images formed by the doubly refracting rhomb differed only in intensity, the colours and the diameters of the rings being exactly the same in both. *Above* the polarising angle, however, the rings in the two images were of complementary colours, the orders of colours in the one beginning from a black centre, and in the other from a white centre. M. Arago also observed that the rings of the same order of colours in the two images had different sizes. When a plate of any substance of intermediate density between the two substances between which it was contained was used, similar phenomena were produced. When the surface of the metallic reflector was slightly tarnished, M. Arago observed a second system of rings with complementary colours, arising from the light irregularly scattered at the metallic surface, as they could be seen in every position of the eye.

Mr. Airy.

Without knowing of these discoveries of M. Arago, Mr. Airy,[3] about twenty years afterwards, published similar results respecting the modification of the rings above and below the maximum polarising angle; and Professor Lloyd has ingeniously observed, that an analogous result "may be obtained by combining (as in Fresnel's experiment, fig. 92,) a metallic reflector with one of glass. The light being polarised perpendicularly to the plane of reflexion, the central band will be white, when the angle of incidence is below the polarising angle of the glass; at the polarising angle, the interference bars will vanish altogether; and beyond that incidence they will reappear with a *dark* centre in place of a white one. This method of observation would seem to be peculiarly adapted to the investigation of the change of phase produced by metallic reflexion at various incidences."[1]

Professor Lloyd.

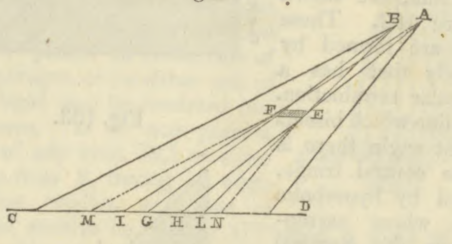
A consideration of Fresnel's expressions, which had led Mr. Airy to make his experiments with a metallic surface, led him also to expect that when the rings were formed between two transparent surfaces of different refractive powers, and when the light was polarised perpendicularly to the plane of incidence, the rings should be *black centred* at incidences below the maximum polarising angle of the least refractive surface, or greater than that of the highest refractive surface, and should be *white*-centred, when the angle of incidence was between these angles. By forming the rings between plate glass and diamond, Mr. Airy found his anticipations correct. In the course of these experiments Mr. Airy observed that the rings did not disappear at the polarising angle of diamond, but that the first black ring contracted as the incidence was gradually increased, and at last took the place of the central white spot. Hence he concluded that there is still some light reflected at the maximum polarising angle of diamond, and that this body has no angle of complete polarisation. See page 376, col. 2.

SECT. III.—*On the Diffraction or Inflexion of Light.*

Diffraction of light.

M. Grimaldi, to whom we owe the discovery of the interference of light, likewise made some important experiments on what is called the diffraction or inflexion of light. Having admitted a ray of solar light into a dark room, through a small hole AB, he placed in the conical beam ABCD an

Fig. 99.



Fringes without the shadow.

opaque body EF. The shadow of this body was not bounded by the straight lines AEH, BFG, nor by the penumbra IL formed by the lines BEI, AFL, but was enlarged to MN, and was much greater than it should have been, if formed by rays passing in straight lines past the edges of the body. Without the shadow of the body there were three fringes of coloured light, the broadest and most luminous of which, next to the shadow X, fig. 100, was MNO. There was no colour in the middle at M, but it was *blue* at the side NN, and *red* at the other side OO. The second fringe

[1] *Phil. Trans.* 1807, 1809, 1810.

[2] Tom. iii.

[3] *Cambridge Transactions*, 1832.—The following note upon this paper we confess ourselves unable to understand, "I have carefully verified," says Mr. Airy, "this assertion, (that it is indifferent whether the light is polarised before or after reflexion) because I think that it leads to important theoretical conclusions. If polarisation were a *modification* of light (as Dr. Brewster and others have supposed,) it might be conceived that polarisation before incidence, might destroy its power of producing rings at a certain angle, or might change the tints; but when the reflexion is performed, and the rings are actually visible to the eye with a dark centre, it seems quite inconceivable that any *modification* or *physical change* in the light should make that centre appear white. The satisfactory explanation is, that polarisation is a *resolution* of the vibrations into two sets at right angles to each other, performed in such a manner that the two sets can in general be separately exhibited, and that in this instance only one is transmitted to the eye." The authors criticised in the preceding extract, viz. Malus, Young, Biot, Herschel, and we believe MM. Arago and Fresnel, all considered polarisation as a modification of common light, and if a *modification* certainly a *physical change* without any reference to theory. In every point of view, indeed, the term is philosophical and unexceptionable. If polarisation is a *resolution*, as Mr. Airy affirms, of vibrations *in an infinite number of planes*, into *two sets at right angles to each other*, which we do not question, this is certainly a pretty considerable modification and a very remarkable physical change. As we have nothing to do with theories in describing phenomena, we must continue to use the terms which have been regarded as appropriate by our contemporaries.

[4] *Report on Optics*, British Association Reports, *Rep.* 4, 1835, p. 366.

Periodical Colours.

QPR was narrower than MNO. It was colourless in the

Fig. 100.

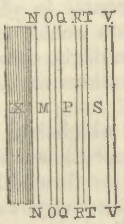


Fig. 101.

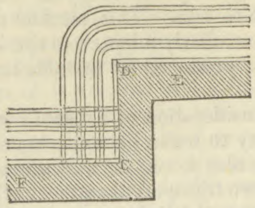
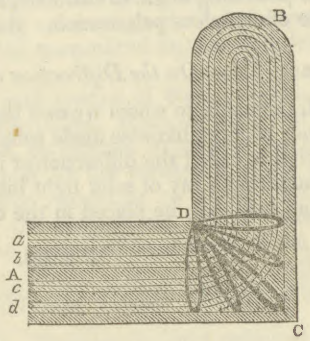


middle at P, faintly blue at QQ, and faintly red at RR. The third fringe STV resembled the other two, but was the narrowest and the faintest in its colours. They were bent round the edges of the body, as shewn in fig. 101.

Fringes within the shadow.

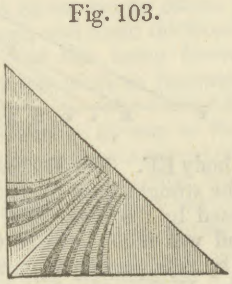
Grimaldi likewise discovered fringes within the shadow, which were best seen when the body was long, the light great, and its distance from the aperture considerable. These internal fringes increased with the breadth of the body, and they became narrower when they increased in number. They were bent round the angles of the body, as shewn in fig. 102, where ADBC is the shadow, and *a*, *b*, *c*, *d* the internal fringes. Short lucid streaks were seen proceeding, as it were, from the angle D, and returning to it, as shewn in the figure.

Fig. 102.



What Dr. Young has called the *crested fringes* of Grimaldi, are shewn in figure 103. These fringes are formed by any body that has a rectangular termination. At the line which bisects the right angle there is a white central fringe, bounded by hyperbolic curves, whose asymptotes are the diagonal line, and on each side of this are two or three other bands, disposed in hyperbolic curves, which are convex to the diagonal, and converging in some degree, as they recede from the angular point.

Fig. 103.



Sir Isaac Newton.

In repeating the experiments of Grimaldi, Sir Isaac Newton admitted the sun's light through a small hole in a piece of lead the forty-second part of an inch in diameter; he found the breadth of the shadow of a human hair, which was the 280th of an inch in diameter, to be as follows:—

Distance of the hair from the aperture.	Distance of the paper receiving the shadow from the hair.	Breadth of the shadow.
12 feet............	4 inches	0·01666 inches.
12 —	24 —	0·03572 —
12 —	128 —	0·125 —

Upon comparing the breadths of the fringes without the shadow, and their intervals at different distances, he found them to be nearly in the same proportion, the breadths of the fringes being as the numbers 1, $\sqrt{\frac{1}{3}}$, $\sqrt{\frac{1}{5}}$, &c., and their intervals to be in the same progression. Hence the fringes and their intervals together was as the number 1, $\sqrt{\frac{1}{2}}$, $\sqrt{\frac{1}{3}}$, $\sqrt{\frac{1}{4}}$, &c.

When the hair was surrounded with water, the very same phenomena were seen, and metals, stones, glass, wood, horn, ice, &c., produced the very same fringes. The following was the order of the colours, reckoning from the shadow:—

First fringe,....Violet, indigo, pale blue, green, yellow, red.
Second fringe,..Blue, yellow, red.
Third fringe,...Pale blue, pale yellow, red.

Fringes in homogeneous light.

When homogeneous light was used, Sir Isaac found that the fringes were *largest* in *red* light, *least* in *violet* light, and of an intermediate size in *green* light. In one case, the distance between the middle of the first fringe on each side of the shadow was $\frac{1}{37\cdot5}$ of an inch in *red* light, and $\frac{1}{46}$ in *violet* light.

Knife edges.

From experiments made by Sir Isaac Newton on the light which passed by the edge of a knife, and on that which passed between two knife edges parallel to each other, he concluded that the light of the *first* fringe passed by the edge of the knife at a distance greater than the 100th part of an inch; the light of the *second* at a greater distance than that of the first; and the light of the *third* fringe at a greater distance than that of the second.

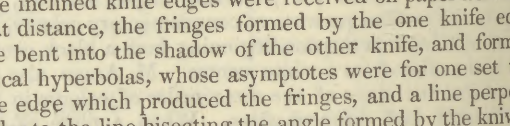
Sir Isaac then stuck into a board the points of two knives with straight edges, so that their edges formed an angle of 1° 47′ 26″, and from the observations which he made on the light which passed between them, he concluded *that the light which forms the fringes is not the same light at all distances of the paper from the knives*, obviously considering each fringe as produced like caustic curves, by the intersection of the inflected rays. When the fringes formed by these inclined knife edges were received on paper held at a great distance, the fringes formed by the one knife edge were bent into the shadow of the other knife, and formed cubical hyperbolas, whose asymptotes were for one set the knife edge which produced the fringes, and a line perpendicular to the line bisecting the angle formed by the knives.

Dr. Thomas Young.

Although many attempts were made during the last century to complete the unfinished labours of Newton on this subject, yet no decided discovery was made till the time of Dr. Thomas Young. This distinguished natural philosopher, in endeavouring to explain the origin of the fringes which surrounded the shadow of the margin of a small circular aperture, conceived that the light nearest its centre was least inflected, and that nearest its edges most; and that another portion of light reflected from the margin of the aperture, and coinciding either exactly or nearly with the direct light, after a circuitous path, would interfere with that light, and produce colour. In November 1803 he confirmed this supposition to a certain extent, in so far as the production of the colours by interference was concerned, by his discovery of the interference of light, as already described.

The fringes formed by inflexion, as observed by Dr. Young, are shewn in fig. 104, where ABCD is the shadow of the

Fig. 104.



inflecting body with its *internal fringes*, which he considered as produced by the light passing on each side of the inflecting body, and bent into the shadow, so as to interfere in the manner already described. This he clearly proved to odical ours.

be the case; but he was less successful in explaining the external fringes between AC and GH, and between BD and EF. He ascribed them to the interference of rays *reflected from the margin* of the inflecting body, with rays which passed by it directly.

Dr. Young examined the *crested fringes* of Grimaldi in the same manner as he did the internal fringes ABCD. He found that when a screen was placed within a few inches of the inflecting angle of the body, so as to receive only one of the edges of the shadow, all the crested fringes disappeared; but if the rectangular point of the screen was opposed to the point of the shadow, so as barely to receive the angle of the shadow, or its extremity, the fringes were in no way affected.

Fresnel

M. Fresnel in France, and M. Fraunhofer at Munich, were simultaneously occupied in studying the inflexion of light, and each of them published the results of their labours, without any knowledge apparently that the other had been similarly occupied. We shall begin by giving an account of Fresnel's experiments.

In place of a small hole, M. Fresnel adopted the ingenious idea of substituting a lens of short focal length, which collected the solar rays into its focus, from which they diverged as from a small luminous aperture. When bodies were placed in this bright light, they gave distinct fringes, the magnitude of which he was able to measure at various distances behind the inflecting body, and at various distances of the inflecting body from the lens, simply by viewing the fringes with an eye-glass furnished with a micrometer, instead of rendering them dull by receiving them upon paper. In this manner he measured their breadths within the one or two-hundredth part of a millimeter. He traced the external fringes up to their very origin, and by the aid of a lens of a short focus, he saw the *third* fringe at the distance of less than the one-hundredth part of a millimeter from the edge of the inflecting body. M. Fresnel made also the important discovery that the phenomena varied with the distance of the inflecting body from the radiating or luminous point, as will be seen from the following measures:—

Distance of the inflecting body from the focus of the lens.	Distance behind the body where the inflexion was measured.	Angular inflexion of the red rays of the first fringe.
0 feet 4 inches..........	3.281 feet..............	12′ 6″
19 — ·48 —	3·281 —	3 55

from which it appears that the rays experience a less degree of inflexion in proportion to the distance of the inflecting body from the radiant point.

When the inflecting body was kept at a fixed distance from the lens, M. Fresnel measured the inflexion of the same fringe at different distances behind the inflecting body, and the result of these measurements was, *that the successive positions of the same fringe did not lie in a straight line, but formed a curve, whose concavity is turned towards the inflecting body.* The successive positions of the same fringe in all the orders of colours he found to be hyperbolas, having the radiating point and the edge of the inflecting body for their common foci. In some of these curves the maximum deviation from a straight line was the twenty-fifth part of an inch, or nearly fifty times greater than the error of observation.

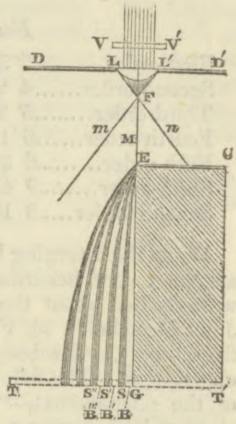
In explaining the exterior fringes, M. Fresnel agreed with Dr. Young in supposing that rays reflected from the margin of the inflecting body interfered with the direct rays; but he was afterwards led, both by theory and experiment, to renounce this opinion.

He found that the fringes were absolutely independent of the curvature of the margin of the inflecting body, and that in cases where the margin was made extremely narrow or sharp, the small quantity of light which it could reflect would be incapable of producing, by its interference with the direct light, such bright fringes as are actually observed. To assure himself of this, he took two plates of steel, the edge of each of which was rounded in one half of its length, and sharp in the remaining half; he placed the rounded portion of one edge opposite the sharp portion of the other, and *vice versa*. Hence, if the position of the fringes depended on the form of the surface, the effect would thus be doubled, and the fringes appear broken in the middle. They were on the contrary perfectly straight throughout their whole length.[1] M. Fresnel was therefore obliged to suppose, and the supposition he found to be perfectly conformable to the undulatory theory, that rays that pass at a sensible distance deviate from their primitive direction, and interfere with those which pass directly by the edge of the body.

Periodical Colours.

In order to settle this question, M. Fresnel compared the results of Dr. Young's hypothesis with those of his own, and he found that the breadth of any fringe of homogeneous light should be on the two hypotheses as 2 to 1·8726, and having measured the diameter of such a fringe, he found his own hypothesis more consistent with observation than Dr. Young's.

Fig. 105.



In order to exhibit to the eye the hyperbolic form of the fringes, we have given a representation of them in fig. A, where LL is a lens of short focus, by which the rays of the sun entering a dark chamber, are refracted to a focus F, from which they again diverge, forming the cone F*mn*. Or the lens may be fixed in a large diaphragm DD′, which may stand on the table before the window at which the sun's light enters. By means of a coloured glass VV′ placed on either side of the diaphragm, or on either side of F, the light may be rendered homogeneous. If we now place a screen of any kind, EC, at some distance from F, having its edge somewhat smaller, and free of dust, and receive its shadow GT′ upon a sheet of paper, or any white ground, TT′, or on a glass plate roughened with emery, we shall obtain the section of the fringes formed by diffraction. The line FEG, which is the geometrical shadow, is not the real shadow. On the side of it towards GT′, the paper will not appear *black*, but illuminated with a visible shade, which goes on decreasing nearly uniformly for a considerable distance. On the other side of EG there are several fringes or alternations of light and darkness. The *first* fringe B parallel to the shadow is *bright*, then a band S almost entirely black, which is the *black fringe* of the *first order*, then a second *bright* fringe B′, which is followed by the *second black fringe* S′. These alternations continue to a great distance from G, so that even the sixteenth or seventeenth order may be observed, the bright fringes becoming less coloured, and the black ones more luminous, till they are no longer visible.

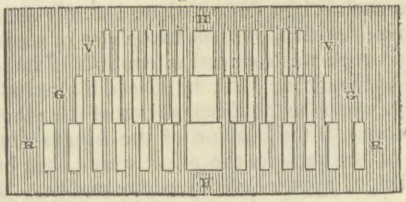
By varying the distance of the paper TT′ from the screen EC, or of the screen from the focus F, the same fringes are produced with certain variations depending on their distances, the fringes being propagated in hyperbolas, as shewn in the figure. The fringes are *largest* in *red* R, smallest in *violet* V, and of an intermediate size in *green* light G, as re-

[1] *Mémoire sur la Diffraction*, p. 370. Prof. Lloyd's Report, *ut antea*.

Periodical Colours.

presented in fig. 106, where they are shewn as on each side of the shadow of a human hair HH.

Fig. 106.



The following table shews the angular distances of the seven first fringes from the inflecting body EC, and the geometrical shadow :—

For Red Light.

	Angles, FE = 1000 millimetres.	Angles, FE = 100 millimetres.	Angles, FE = 10 millimetres.
First order	3′ 35″	11′ 20″	35′ 51″

Sir John Herschel.

When the diverging light passes through a small circular aperture, very beautiful phenomena are observed, which were studied about the same time by M. Fresnel and Sir John Herschel.[1] M. Fresnel had deduced the phenomena from theory, and subsequently confirmed his deductions by experiment. The following is Sir John Herschel's[2] account of the phenomena:—"Suppose," says he, "we place a sheet of lead, having a small pin-hole pierced through it, in the diverging cone of rays from the image of the sun, formed by a lens of short focus, and in the line joining the centres of the hole and focus prolonged, place a convex lens or eye-glass, behind which the eye is applied. The image of the hole will be seen through the lens as a brilliant spot, encircled by rings of colours of great vividness, which contract and dilate, and undergo a singular and beautiful alternation of tints, as the distance of the hole from the luminous point, on the one hand, or on the eye-glass, on the other, is changed. When the latter distance is considerable, the central spot is white, and the rings follow nearly the order of the colours of thin plates. Thus, when the diameter of the hole was about 1-30th of an inch, its distance (a) from the luminous point about six feet six inches, and its distance (b) from the eye-lens twenty-four inches, the series of colours was observed to be,

"1st order. White, pale yellow, yellow, orange, dull red.

"2d order. Violet, blue (broad and pure), whitish, greenish yellow, fine yellow, orange red, very full and brilliant.

"3d order. Purple, indigo blue, greenish blue, pure brilliant green, yellow green, red.

"4th order. Good green, but rather sombre and bluish, bluish white, red.

"5th order. Dull green, faint bluish white, faint red.

"6th order. Very faint green, very faint red.

"7th order. A trace of green and red.

"When the eye-lens and hole are brought nearer together, the central white spot contracts into a point and vanishes, and the rings gradually close in upon it in succession, so that the centre assumes in succession the most surprisingly vivid and intense hues. Meanwhile the rings surrounding it undergo great and abrupt changes in their tints. The following were the tints observed in an experiment made some years ago, (July 12, 1819), the distance between the eye-glass and luminous point ($a+b$) remaining constant, and the hole being gradually brought nearer to the former :—

$b=$	Colour of the central Spot.	Surrounded by
24·00	White.	Rings as in the foregoing description.
18·00	White.	The two first rings confused, the red of the 3d, and green of the 4th orders splendid.
13·50	Yellow.	Interior rings much diluted, the 4th and 5th greens, and 3d, 4th, and 5th reds, the purest colours.
10·00	Very intense orange.	All the rings are now much diluted.
9·25	Deep orange red.	The rings all very dilute.
9·10	Brilliant blood red.	The rings all very dilute.
8·75	Deep crimson red.	The rings all very dilute.
8·36	Deep purple.	The rings all very dilute.
8·00	Very sombre violet.	A broad yellow ring.
7·75	Intense indigo blue.	A pale yellow ring.
7·00	Pure deep blue.	A rich yellow.
6·63	Sky blue.	A ring of orange, from which it is separated by a narrow sombre space.
6·00	Bluish white.	Orange red, then a broad space of pale yellow, after which the other rings are scarcely visible.
5·85	Very pale blue.	A crimson red ring.
5·50	Greenish white.	Purple, beyond which yellow, verging to orange.
5·00	Yellow.	Blue, orange.
4·75	Orange yellow.	Bright blue, orange red, pale yellow, white.
4·50	Scarlet.	Pale yellow, violet, pale yellow, white.
4·00	Red.	White, indigo, dull orange, white.
3·85	Blue.	White, yellow, blue, dull red.
3·50	Dark blue.	Orange, light blue, violet, dull orange.

"The series of tints exhibited by the central spot is evidently, so far as it goes, that of the reflected rings in the colours of thin plates; the surrounding colours are very capricious, and appear subject to no law."

We owe also to Sir John Herschel the following beautiful experiment with two equal apertures placed near each other. The rings are formed about each as in the case of

[1] Sir John Herschel's experiment was made on the 12th July 1819, but was not published till 1825.

[2] *Treatise on Light*, sect. 729, 730.

Periodical Colours.

one aperture, but these are accompanied with a set of straight parallel fringes, bisecting the interval between their centres, and perpendicular to the line joining their centres. Two other sets of similar fringes appear in the form of a St. Andrew's cross, forming equal angles with the first set, as shewn in Plate CCCLXXXI. fig. 5. When the apertures are unequal, as in fig. 6, these fringes assume the form of hyperbolas, having the aperture in their common focus. By varying the number and shape of the apertures, the phenomena became exceedingly beautiful.

late CCLXXXI. igs. 5, 6.

I. Poisson

M. Poisson deduced from theory that the centre of the shadow of a small circular opaque disc, exposed to light emanating from a single luminous point, would be precisely as much illuminated by the diffracted light as it would be by the direct light, if the disc were removed. By using a small disc of metal, cemented to a clear and homogeneous plate of glass, M. Arago confirmed this very remarkable result.

I. Arago.

We owe to M. Arago a series of beautiful discoveries respecting the influence of transparent screens in the phenomena of inflexion. When a thick piece of glass was used as a screen on one side of the inflecting body, the rings wholly disappear, as if the screen were opaque. If the screen is very thin, like a film of sulphate of lime or mica, the fringes still remain visible, but shift their places, and are moved from the side where the screen is interposed.

If we make this experiment on the fringes produced by two apertures, we have only to cover one of the apertures with the screen. The same effect, however, will be produced, if we cover both apertures with screens of different thicknesses. In this case the fringes will shift their places from the thicker plate, without suffering any other change.

This beautiful property has been most ingeniously employed by MM. Arago and Fresnel, in measuring the refractive powers of different gases. For as the displacement of the coloured fringes depends on the refractive power, as well as thickness of the plate, its refractive power may be computed from the displacement. In the same manner, if one of the interfering rays are made to pass through tubes filled with different gases, while the other does not, the displacement produced by the gas will give a measure of the refractive power of the gaseous medium.

aunhofer

We come now to give some account of the experiments of Joseph Fraunhofer, made with instruments of extreme accuracy, and furnishing data of the highest importance in physical optics.[1]

The apparatus employed by Fraunhofer was a repeating theodolite, whose vernier read off to 4″. In the centre of the circle, but above it, this instrument carries a flat circular plate six inches in diameter, having its axis coincident with that of the theodolite, and graduated separately to 10″. In the middle of this disc is placed a metallic screen, in which the necessary apertures are made, and which is in the axis of the theodolite. The divisions of this disc serve to measure if necessary the angle of incidence of the rays. A telescope, having an object-glass of twenty lines in aperture, and 16·9 inches in focal length, is placed three-and-a-half inches from the centre of this disc. This telescope is placed firmly on the alidade of the divided circle, whose diameter is twelve inches, and the whole is counterpoised. The axis of the telescope is exactly parallel to the horizon, as well as to the plane of this circle. The magnifying power which he employed was from thirty to fifty times. The instrument did not communicate with the floor of the room, from which it was wholly insulated. The heliostate was placed in the prolongation of the optical axis, at a distance of 38 feet 7½ inches from the centre of the theodolite. In order to make the heliostate follow the sun in his hourly motion, the observer could move the screw of the mirror by means of a long rod of iron, which extends from the heliostate to the theodolite, and with this apparatus he could also vary at pleasure the intensity of the solar light. The opening of the heliostate is vertical, being two inches high, and commonly from the 50th to the 100th of an inch.

Periodical Colours.

By means of an achromatic microscope, magnifying 110 times, Fraunhofer measured the aperture in the metallic screen, which he did to the fifty-thousandth, and sometimes to the hundred-thousandth part of an inch, provided the body was very fine at its edge.

Fraunhofer's first observations were made with a single slit, which was placed before the object-glass of the telescope, which had been previously directed to the aperture in the heliostate, so that the aperture was bisected by the wire of the micrometer. He then saw the fringes shewn in fig. 7, Plate CCCLXXXI. The middle fringe or band $L^{I}L'$ bisected by the micrometrical wire K, was *white*, becoming yellow towards L^{I} and L^{II}, where it was red. In the space L^{I} L^{II} there is a spectrum with very lively colours, viz. *indigo* near L^{I}, then *blue*, *green*, *yellow*, and *red*, near L^{II}. The spectrum in L^{II} L^{III} is much less intense, viz. *blue* near L^{II}, and *yellow*, *green*, and *red* near L^{III}. The spectrum in the space L^{III}, L^{IV}, is still fainter, being *green* on the side L^{III}, and *red* on the side L^{IV}. A great number of spectra follow these, becoming fainter and fainter, and losing themselves in a band of light, which is spread over a great space. All these spectra on both sides of K are perfectly equal, and consequently symmetrical. Both the colours and the spectra shade into one another imperceptibly. The following table contains the average of the distances L^{I}, L^{II}, L^{III}, and L^{IV}, from the central line, all of them being equal, the measures being taken from the red extremity of each spectrum, so that if we wish to have the angle of deviation of L^{II} from KK we have only to multiply the value of L in the table by 2, and so on.

Width of the aperture in parts of a Paris inch.	Breadth of each spectrum or values of KL_{I}, EL^{II}, &c.	Product of the aperture by the deviation L.
0·11545	—37″·66	0·0000210
0·06098	1—11 ·17	0·0000210
0·03690	1—56 ·6	0·0000209
0·02346	3—4 ·43	0·0000210
0·01237	5—48 ·7	0·0000209
0·01210	6—1 ·84	0·0000212
0·01020	6—57 ·3	0·0000206
0·00671	11—6 ·4	0·0000217
0·00642	11—12 ·2	0·0000209
0.00337	21—10 ·3	0·0000207
0·00308	23—32 ·7	0.0000211
0·00218	33—40	0·0000213
0·00215	35—17	0.0000220
0·00114	1 4—53	0·0000215

From these observations, M. Fraunhofer deduces the following conclusions:

1. *That the angles of deviation of the luminous rays which pass through a single aperture, are in the inverse ratio of the width of that aperture.*

2. *That when a ray is diffracted in passing through a narrow aperture, the distance of similar rays from the middle in the several spectra, form in each case an arithmetical progression, whose difference is equal to the first term.*

3. *That if γ is the aperture, the arches L^{I}, L^{II}, or the deviation of the inflected rays, are in general for the radius of a circle equal to* 1, $L^{I}=\frac{0{\cdot}0000211}{\gamma}$, $L^{II}=2.\frac{0{\cdot}0000211}{\gamma}$

$$L^{III}=3.\ \frac{0{\cdot}0000211}{\gamma}.$$

By observing whether the micrometer were appeared or disappeared in the different spectra, Fraunhofer ascertained that the spectra nearest KK, are not composed of homo-

[1] *Neue Modifikation des Lichtes durch gegenseitige Einwirkung und Beugung der Strahlen, und Gesetze derselben.* Von Jos. Fraunhofer in Munchen. Without a date.

Periodical Colours.

geneous light, but that it becomes more and more homogeneous at greater distances from the axis.

Our author next proceeds to describe the phenomena observed when the two edges which form the narrow aperture, *are at different distances* from the object-glass. When the effective width of the aperture thus formed, is from the 25th to the 50th of an inch, the spectra are the same as those before described; but when the opening becomes less, the spectra on one side of the axis become wider, horizontally than those on the other side. When the apparent aperture was extremely narrow, the spectra on one was two or three times wider than those on the other. By continuing to close the distant edges, the longest spectra begin to disappear successively, so that the fifth spectrum for example, fills almost suddenly the whole field of the telescope, till it ceases to be visible, then the fourth spectrum presents the same phenomena, then the third, and so on. During these changes the spectra on the other side remain unchanged, but when all the former have vanished, *they also disappear in their turn, not successively, but all at once*, which happens when no light passes between the edges. The large spectra are always on the side of the screen, which is nearest the object-glass.

When the apertures, both in the heliostate, and in front of the object-glass, were small circular ones, a system of rings are produced, absolutely the same as those of thin plates, with this difference only, that the centre is *white* in place of *black*. The rays increase in size as the apertures diminish. By varying the apertures he obtained the following results:

1. *That the diameter of the coloured rings are in the inverse ratio of the diameter of the apertures.*

2. *That the distances of the extreme rings (of any given refrangibility) from the centre form an arithmetical progression, whose difference is smaller than the first term.*

3. *That if γ is the diameter of the aperture in Paris inches, we shall have*

$$L=\frac{0{\cdot}0000214}{\gamma}=L^{II}-L^{I}=L^{III}-L^{II}, \text{ \&c.}$$

$$L^{I}=\frac{0{\cdot}0000257}{\gamma}$$

$$L^{II}=\frac{0{\cdot}0000257}{\gamma}+L, \text{ and so on.}$$

Spectra produced by gratings andgrooves

The most important and interesting of Fraunhofer's researches, are those which relate to the spectra produced by gratings, consisting of a number of parallel wires placed parallel also to the narrow linear aperture in the heliostate. He formed these gratings of fine wires stretched across a rectangular frame; the two shorter ends of the frame consisted of two fine screws made with the same die, and having 260 threads in an inch. By placing a wire in each thread he ensured their exact parallelism. The diameter of each wire was 0·002021 of a French inch, and the edge of each wire was distant from the adjacent edge 0·003862 of an inch. The aperture of the heliostate was two inches long, and the 100th of an inch wide, and the frame of wires was placed before the object-glass, so that no other light could be admitted but through them. Fraunhofer was astonished at the phenomena which he saw. He saw the colourless line of light A, Plate CCCLXXXI, fig. 8, in the aperture of the heliostate, exactly as if no wires had been interposed, and at some distance from it on both sides *a great number of coloured spectra exactly similar to those produced by a good prism.* They were larger in proportion to their distance from the central bright line, and they diminished in intensity in the same proportion. A part of these spectra are shewn in figure 8, where A is the aperture of the heliostate, absolutely without colours. On each side of A the spectra are perfectly symmetrical. When the apparatus is well made, the space

Plate CCCLXXXI. Fig. 8.

AH^{I} is absolutely black. The *first* spectrum occupies the space H^{I}, C^{I}; H^{I} being the usual limit of the violet, and C^{I} that of the red. Between H^{II} and C^{II}, there is a second spectrum twice as long as the first; the order of the colours being the same, but their intensity a little less. The third spectrum occupies the space between C^{II} and F^{IV}, but a part of its violet rays are mixed with the red of the *second* spectrum, and also a part of the *red* rays of the *third* with the *blue* rays of the *fourth* spectrum. The *fourth* spectrum is seen between F^{IV} and D^{IV}, its *blue* extremity losing itself in the *third*, and its *red* extremity in the *fifth* spectrum. Many other spectra succeed these, and when the apparatus is good, *thirteen* may be easily reckoned on each side of A.

But what is the most interesting fact, when the apparatus is good, and the adjustments correct,—the *fixed dark lines in the prismatic* spectrum are seen at C^{I}, D^{I}, these lines being the same as those similarly marked in Plate CCCLXXXI, fig. 1. It is remarkable, however, that A is not seen, a fact which M. Fraunhofer neither notices nor explains. The lines both great and small, are absolutely the same, both in this and the prismatic spectrum, though their distances are widely different.

In a grating in which γ, the distance between the wires is 0·000628, and δ, or the diameter of the wires 0·001324, the following are the distances:

	Diffracted Spectrum.	Water Spectrum.
Distance between the lines B^{I} and C^{I}	2′ 2″·6	1′ 3″·3
—— C^{I} — D^{I}	4 23 2	2 41
—— D^{I} — E^{I}	4 5 ·2	3 16
—— E^{I} — F^{I}	2 39 ·9	2 47
—— F^{I} — G^{I}	3 37 ·6	5 57
—— G^{I} — H^{I}	2 12 ·5	4 14
Total length from B^{I} to H^{I}	19 1 0	19 1 ·3

The diffracted spectrum is therefore a very extraordinary one. The green space from E to F, is almost exactly the same in both, but all the less refrangible spaces are greatly expanded in the diffracted spectrum, and the more refrangible spaces greatly contracted, the *red* space CD in the diffracted spectrum being *twice as great* as in the water spectrum; and the *violet* space in the water spectrum twice as small.

M. Fraunhofer repeated the above experiments with *ten* different gratings, in which the breadth of the wires and the spaces between them were varied, and he deduces from them the following laws:

1. *For two different gratings in which the parallel wires are of the same size and placed at equal distances, the magnitude of the spectra which arise from the reciprocal influence of a great number of rays diffracted by narrow apertures, and their distances from the axis are in the inverse ratio of the intervals $\gamma+\delta$, that is the space from the middle of one of the openings to the middle of the other.*

2. *In all the perfect mean spectra, or those in which the fixed lines are seen, the distances between the coloured rays of the same nature in the different spectra, or between the same fixed lines in them, form an arithmetical progression, whose distance is equal to the first term.*

3. *In gratings in which the diameter δ of the wires and the distance γ between them is expressed in Paris inches, the first term of the progression for the fixed lines* B, C, D, E, *or those rays which have the corresponding degrees of refrangibility is represented by the following numbers.*

$$B=\frac{0.00002541}{\gamma+\delta};\quad C=\frac{0.00002425}{\gamma+\delta};\quad D=\frac{0.00002175}{\gamma+\delta};$$

$$F=\frac{0.00001943}{\gamma+\delta};\quad F=\frac{0.00001789}{\gamma+\delta};\quad G=\frac{0.00001585}{\gamma+\delta};$$

$$H=\frac{0.00001451}{\gamma+\delta}.$$

If we represent the numerator of each of these expressions by a, the angle of deviation of one of the same coloured rays in the *first* spectrum by ϑ'', in the *second* by ϑ'', in the *third* by ϑ''', we have generally

$$\vartheta' = \frac{\omega}{\gamma+\delta}, \quad \vartheta'' = \frac{\omega}{\gamma+\delta}, \text{ \&c.}$$

If ν stands for the number of the spectrum, ν being $=0$ for the axis, $=1$ for the first spectrum, 2 for the second spectrum, and if we put $E=\gamma+\delta$ we shall have in general,

$$\vartheta(\nu) = \frac{\nu\alpha}{\varepsilon}.$$

The preceding results having been obtained with angles so small that the arcs and their sines and tangents are nearly in the same proportion, M. Fraunhofer began a new series of experiments with the view of obtaining spectra, in which the angles should be larger and by which he might determine whether it was the arcs or their sines or tangents which had the proportions assigned by the experiments.

This inquiry rendered it necessary to obtain much finer gratings than those he had used. He therefore coated a plate of glass with two or three folds of gold leaf in order to have the interstices filled up, and by a peculiar arrangement he traced upon the glass parallel lines in which ε was $=0.00114$ of an inch. When the lines were drawn closer, no gold remained upon the glass. With this system the spectra were larger, and the fixed lines distinctly seen, but they did not answer his purpose. He therefore thought of spun glass which answered as well as wires; and having covered a plate of glass with a thin coat of fat, so thin that it could scarcely be seen, he traced parallel lines upon it, the intervals of which were only half the size of those on the gold leaf. The spectra produced by this system of lines gave the fixed lines very distinctly, so that their distances from the axis could be accurately measured; but he could not succeed in tracing either upon a layer of fat or black varnish lines closer than this. He at last succeeded in his object of tracing a finer system of lines by using a diamond, with which, by the aid of a machine, he traced lines so fine upon the surface of glass, that they could not be seen by the most powerful compound microscope. In this way he obtained a set of several thousand lines in which $\varepsilon=0.0001223$ of an inch, and which are at distances so very equal, that the fixed lines in the first and second spectrum are clearly seen.[1]

With the system when $\varepsilon=0.0001223$, and the number of lines 3601, the fixed line D is seen double in the first spectrum.

When the light fell vertically on this grating, Fraunhofer obtained the following measures:

Names of fixed lines.	Distance of fixed lines from the axis A. Fig. 8, Plate 1.	Distance of lines in first spectrum.
C^{I}	11° 25′ 20″	C^{I} from D^{I}
C^{II}	23 19 42	1° 10′ 49″
D^{V}	10 14 31	D^{I} from E^{I}
D^{II}	20 49 44	1 5 31
E^{I}	9 9 0	E^{I} from F^{I}
E^{II}	18 32 34	0 32 54
F^{I}	8 26 6	F^{I} from G^{I}
F^{II}	17 3 34	0 58 47
G^{I}	7 27 19	G^{I} from H^{I}
G^{II}	15 3 9	0 34 43
H^{I}	6 52 36	

With this grating, the *third*, *fourth*, and following spectra were well seen, but the fixed lines could not be seen with sufficient distinctness for accurate measurement in those beyond the *first* and *second*.

He therefore used another grating in which $\varepsilon=0.005919$ of an inch; and when the light fell upon it vertically, he obtained the following results for the first five spectra, with the lines D, E, and F, for the first four, with E, for the first three with F and G, and the first two for H.

Names of fixed lines.	Distance of fixed lines from axis.	Names of fixed lines.	Distance of fixed lines from axis.
C^{I}	2° 20 57	E^{V}	9 28 3
D^{I}	2 6 30	F^{I}	1 44 19
D^{II}	4 13 7	F^{II}	3 28 45
D^{III}	6 20 7	F^{III}	5 13 23
D^{IV}	8 27 43	F^{IV}	6 58 18
D^{V}	10 35 53	G^{I}	1 32 22
E^{I}	1 53 7	G^{II}	3 4 57
E^{II}	3 46 17	G^{III}	4 37 30
E^{III}	5 39 50	H^{I}	1 27 0
E^{IV}	7 33 41	H^{II}	2 50 11

all the observations made with both the systems of lines are represented by the expression

$$\operatorname{Sin} \vartheta^{(\nu)} = \frac{\nu\omega}{}.$$

That is with rays falling vertically, the sines of the angle of deviation of any fixed line or ray of definite refrangibility from the axis in the different spectra which succeed others, are as the numbers 1, 2, 3, 4, 5.

The last of these systems of lines has the remarkable property of having all the spectra on one side of the axis twice as luminous as those on the other. Fraunhofer supposed that one of the sides of each line had been sharper than the other, and confirmed this opinion by tracing lines on a layer of fat, so that one line was less sharp than the other, and it produced the same inequality in the intensity of the light of the spectra on each side of the axis.

If the ray does not fall vertically upon the system of grooves or lines, but is inclined to it in a plane which intersects the parallel lines vertically, the same effect is produced as if the distance between the middle of the lines or ϵ were diminished in the ratio of the radius to the cosine of the angle of incidence. Hence *the distance of the spectra from the axis increases as the cosine of the angle of incidence.* If σ therefore is the angle of incidence, then we have $\sin \vartheta^{(\nu)} = \frac{\nu a}{\epsilon \cos. \sigma}$. This, however, is only true when the system of lines is coarse and σ not very large. But in fine systems of lines it is otherwise, the spectra on both sides of the axis are no longer symmetrical, and in the system where $\varepsilon=0.0001223$, when σ is $=55°$ we have the deviation of D′ on one side of the axis is $=15°16'$, and on the other side of the same axis 30° 33′.

Hitherto we have treated of spectra formed by the light transmitted through the gratings, or through plates of glass with systems of lines etched upon one of its surfaces. But M. Fraunhofer examined also the spectra produced by *reflexion* from the etched surfaces of the glass plates. For this purpose, he coated the surface of the glass with a black resinous varnish of the same refractive power as the glass. Then when light reflected from the system

[1] M. Fraunhofer remarks that it requires much good fortune even with $\varepsilon=0.0001223$ to find a diamond point which shall trace *several thousands* of such lines without being altered, and he had succeeded only in obtaining one system. It is only by trial that an useful diamond point can be obtained. As every line requires to be drawn singly with great care, the labour of drawing two thousand is enormous. Fraunhofer has drawn lines so close that there are 32,000 of them in a Paris inch. By etching the first and last line of the system somewhat stronger than the rest, our author, by a microscopic apparatus, measured the distance between these two lines, the etching machine itself reading the lines which are etched. In this way knowing the number of lines, viz. 3601, and the distance between the first and last, he obtained ε or the distance between the middle of any two lines.

Periodical Colours.

of lines fell on the object-glass of the telescope, the very same phenomena appeared as when the light passed through the same system of lines at the same angle of inclination, spectra not symmetrical being seen. The intensity of the spectra was still such that the distances of the various lines can be determined with great accuracy.

M. Fraunhofer has noticed it as very remarkable that under a certain angle of incidence a *portion of a spectrum* produced by reflexion, consists of entirely polarised light. This angle of incidence varies greatly for the different spectra, and even still very perceptibly for the different colours of one and the same spectrum. Thus with the glass system of lines where $\epsilon = 0.0001223$, the ray E^{I} in the green part of the first spectrum is polarised when $\sigma = 49°$, but the same green part of the *second* spectrum on the same side of the axis is only polarised when $\sigma = 40°$, and the green part of the first spectrum lying on the opposite side of the axis, is not polarised till $\sigma = 69°$. In this last case the remaining colours of the spectrum are imperfectly polarised. This was less the case in the second spectrum above mentioned where the colour still remained polarised when the angle of incidence was perceptibly altered. In the spectrum where the green light was polarised at 69°, the light was at no angle of incidence so completely polarised as in the first spectrum at 49°. With a system of lines in which ϵ is larger than the one above mentioned, the green rays in the spectra already referred to, are polarised at totally different angles of incidence.

A very singular consequence arises from the formula deduced from theory by M. Fraunhofer, and representing his experiments. If the distance ϵ between the lines is less than the length of an undulation, and the light falls vertically on the grating, so that $\sigma = o$, it follows that *no coloured ray remains visible*, however the light may fall, and only the *white* light becomes visible in the axis. Hence all scratches or inequalities on polished surfaces can produce no spectra, or no disturbance in the light which the surface refracts or reflects, and consequently no imperfection in the images which they form. M. Fraunhofer likewise draws the conclusion "that it would be impossible by any means to render such inequalities (those less than ω) visible," and that a microscopic object, the diameter of which is $= \omega$, and consists of two parts, cannot be recognised as consisting of two parts. "This," he adds, "shews us the limits which are set to vision through microscopes." This result, if clearly established, would be a very remarkable one.

It is very obvious, that if the distances of the etched lines or the wires in gratings are unequal, the *larger* distances ϵ will give *smaller* spectra, and the *smaller* distances ϵ *larger* spectra, which will be mixed with each other. Fraunhofer, however, conceived it would be interesting to know what would happen if the intervals ϵ were *regularly unequal*, that is, if the unequality in the distances were regularly repeated in equal parts. With this view he etched parallel lines in various ways, regularly unequal upon plates of glass covered with gold leaf. If the distances between the lines are expressed by ϵ', ϵ'', ϵ''' and if one of the equal parts, which consists of unequal ϵ's is expressed by $\epsilon' + \epsilon'' + \epsilon''' - - - + \epsilon^n$ then the distances of the various spectra were found by experiment to be

$$\text{Sin. } \vartheta = {}^{(\nu)} \frac{\nu \omega}{\epsilon' + \epsilon + \epsilon^n - - - + \epsilon^n}$$

The phenomena of spectra thus produced are chiefly remarkable on account of their different intensity. With some systems of lines of this kind, *several spectra or parts of them may be wholly wanting*, or have so slight an intensity that they are not easily observed, whilst the succeeding ones again become very intense. Owing to this cause, the fixed lines in these spectra may be observed. In the usual systems consisting of equal spaces ϵ, the lines C^{XII}, F^{XII} or the fixed lines C, F, in the twelfth spectrum can be seen; but with a regularly unequal system of lines, where every division consists of three shades ϵ different among themselves, and are as 25 : 33 : 42, the lines C^{XII}, D^{XII}, E^{XII}, and F^{XII} are seen with such distinctness that their distances from the axis can be accurately measured. The reason of this is, that with such systems of lines, the tenth and the eleventh spectra are almost wholly wanting. With this system of lines, indeed, Fraunhofer saw E^{XXIV} or the line E in the 24th spectrum so distinctly that its distance could be measured.

M. Fraunhofer, by means of concentric circular lines etched upon glass at equal distances, and by making the aperture in the heliostate circular, has produced circular spectra with circular fixed lines. Their distances from the axis are in the same proportion as in the spectra produced by parallel lines.

When the gratings and systems of lines are immersed in fluids, the same phenomena are produced, but the distances of all the spectra from the axis are diminished in the inverse ratio of the indices of refraction.

Fraunhofer has given also some fine drawings of a beautiful class of phenomena produced by the diffraction of light passing through round and quadrangular apertures either singly or arranged regularly. When a plate of brass perforated with two equal apertures 0·02227 of an inch in diameter, and 0·03831 distant, is placed in front of the object glass, and the aperture of the heliostate round, the extraordinary appearance shewn in fig. 9, plate CCCLXXXII, was seen. It consisted of 65 elliptical spectra distributed in concentric rings, the outermost of which contains 28 spectra, the next 20, the next 12, and the central one five. When the circular apertures are arranged so as to correspond with the four angles of a square, the effect produced is similar to fig. 10.

Plate CCCLXXXII. fig. 9.

Fig.

One of the most splendid figures of this kind is produced by crossing two gratings with the wires at right angles to each other, a circular image is covered with narrow spectra radiating from the centre, but occupying only parts of different radii. The spectra are rectangular of about a line wide, and from five lines to five inches long. The violet end of each is towards the centre. In some places the spectra touch and overlap each other, but the greater number are insulated.

Our limits will not permit us to pursue this most curious subject any farther, and we must refer our readers to Fraunhofer's own work,[1] and to another recently published by Schwerd of Spires in 1835,[2] in which he has given drawings of an immense variety of beautiful phenomena, all of which are capable of being explained by the undulatory theory.

As the various phenomena of diffraction observed by Arago, Fresnel, Young, Fraunhofer, and Schwerd, are susceptible of being explained by the undulatory theory, even facts of the same class, and having a similar origin, cannot possess much interest in our inquiries into the physical causes to which they must be ultimately referred.

Recent discoveries.

We shall now proceed, however, to give an account of a new series of facts discovered by Sir David Brewster, of which the undulatory theory is not capable in its present form of giving the least explanation, and we must there-

[1] See *Edin. Journal of Science*, N. S. No. xiii. p. 101, and No. xiv. p. 251.

[2] *Die Beugungs-ersheinungen, aus dem Fundamental-gesetz dem undulations theorie analytische entwickelt und in Bieldern dargestellt*, Von F. M. Schwerd, Manheim, 1835.

fore consider such facts as peculiarly calculated to throw light on the physical cause of the phenomena.

In all the phenomena of gratings and systems of lines observed by Fraunhofer, the central image of the luminous aperture in the heliostate is white, a result that might have been expected, as that light is reflected from the original surface of the glass, and cannot interfere with any other light. "If the lines," says Fraunhofer, "were so thick that one touched another, and consequently had no space between them, no light could be regularly reflected from the etched surface, and would, as from every other polished surface, be dispersed. Were the intermediate spaces equally wide as the lines, the etched surface could only regularly reflect half as much light as an equal surface of glass that was not etched, therefore the quantity of regularly reflected light from an etched surface of glass, is in proportion to the quantity of light which is reflected from a surface of glass of the same size not etched, or as the width of the spaces between any two neighbouring lines is to the width of these lines."[1]

These conclusions however irresistible they seem to be, are very far from having any foundation. For upon examining a series of several systems of lines or grooves cut on steel for him by the late Sir John Barton, Sir David Brewster observed, that in several of them the central image hitherto described as *white* or colourless, had a distinct colour which was the same in every part of the system. In one of the systems on which there were 1000 lines in an inch, the central image had its tint a *greenish blue* at a perpendicular incidence, which suffered no change by turning round the plate, nor by reflecting the light from different parts of the system. He found the same colours on various other systems of lines, and upon examining them at different angles of incidence, he found that the tints varied with the incidence, being a maximum at a vertical incidence, diminishing as the incidence increased, and disappearing at an angle of 90°. The following were the general results with the grooves on steel :—

Number of grooves in the inch.	Orders and portions of orders of colours from 0° to 90° of incidence.
500	Citron yellow of the first order shading to white.
625	One complete order of colours, together with the reddish yellow of the second order. The colours very faint.
1000	Four complete orders of colours.
1000	One complete order, with blue, green, and yellowish green of the second order.
1250	One complete order, with blue and bluish green of the second order. The colours very faint.
2000	One complete order, together with blue, green, and greenish yellow of the second order.
2500	One complete order, together with the full blue of the second order.
3333	Gamboge yellow of the first order.
5000	One complete order, together with bluish white of the second order.
10,000	One complete order with blue and fainter blue of the second order.

In the third specimen, with 1000 grooves, mentioned in this table, the following were the four orders of colours:—

Colours.	Angles of incidence.
White	90° 0′
Yellow	80 ½
Reddish orange	77 ½
Pink	76 20
Junction of Pink and blue	75 40
Brilliant blue	74° 30′
Whitish	71
Yellow	64 45
Pink	59 45
Junction of pink and blue.	58 10
Blue	56
Bluish green	54 30
Yellowish green	53 15
Whitish green	51
Whitish yellow	49
Yellow	47 15
Pinkish yellow	41
Pink red	36
Whitish pink	31
Green	24
Yellow	10
Reddish	0

These colours are obviously analogous to those of the reflected rings in thin plates, though with a white centre, but they *have not the same composition.* By turning the system of lines round in azimuth, the same colours are seen at the same angles of incidence, and they suffer no change either by varying the distance of the luminous aperture, or the distance of the eye of the observer.

Desirous of seeing what effect would be produced, when the original surface of the steel was almost wholly removed, Sir John Barton executed for our author a specimen with 2000 grooves in an inch, in which this was nearly effected. Unfortunately, however, the diamond point which he used broke before he had executed any considerable space, and the experiments, therefore, with so small a portion, were less complete than could have been desired.

The specimen, however, gave four orders of colours, which were developed at greater angles of incidence than in the preceding table. The following were the results :—

Colours.	Angles of incidence.
White	90° 0′
Straw yellow	
Faint red	
Pink	
First limit of pink and blue	80 00
Blue	
Green	
Yellow	
Red	
Pink	
Second limit of pink and blue	69 40
Blue	
Green	
Yellowish green	
Yellow	
Orange	
Scarlet	
Purple	
Third limit of pink and blue	48 0
Blue	
Brilliant green	
Yellowish green	
Yellow	
Reddish	10 0

The property established by the preceding experiment is certainly one of a very remarkable kind. That a pure and highly polished metallic surface, which reflects light perfectly white, should actually decompose it when the surface is reduced to narrow lines, is inconsistent with every doctrine respecting light. Here there are no rays to interfere,

[1] Fraunhofer, *Edin. Journal of Science*, No. xiii. p.109.

no doubly refracted pencils, and in short, none of the ordinary conditions on which the decomposition of light depends. That the colour does not arise from light that has entered a certain way into the body interfering with that which is regularly reflected, is obvious from the fact, that in two specimens of 2000 grooves in an inch, impressed on *black* wax, the new colours were very distinct, the vertical tint being a greenish yellow of the second order, in one specimen, and a gamboge yellow in the other, in addition to one complete order of colours at greater incidences.

The following experiments, intended to shew the effect of a variable refracting power in the reflecting surface, are calculated to give us some insight into the nature of this new property of light. In the following table Sir David Brewster has described the changes produced upon the colours, by placing different fluids on the reflecting surface:—

No. of grooves in an inch.	Maximum vertical tint without a fluid.	Maximum tint with three different fluids.
$312\frac{1}{2}$	No colour	1. Water; tinge of yellow. 2. Alcohol; tinge of yellow. 3. Oil of cassia; faint reddish yellow.
500	Citron yellow of first order	1. Water; tinge of red. 2. Alcohol; diluted pink. 3. Oil of cassia; a bluer pink.
625	Reddish yellow of second order	1. Water; faint pink of second order 2. Alcohol; ditto more pink. 3. Oil of cassia; bluish pink of second order.
1,000	Yellowish green of second order	1. Water; pinkish red, second order. 2. Alcohol; brilliant pink, ditto. 3. Oil of cassia; greenish blue, third order.
1,250	Bluish green, faint	1. Water; yellow, second order. 2. Alcohol; yellower. 3. Oil of cassia; yellowish pink.
2,000	Greenish yellow, second order	1. Water; brownish red, second order. 2. Alcohol; pinkish red, ditto. 3. Oil of cassia; greenish blue.
2,500	Blue, second order	1. Water; dilute green. 2. Alcohol; greenish white, second order. 3. Oil of cassia; bright gamboge yellow.
3,333	Gamboge yellow, first order	1. Water; pinkish red, first order. 2. Alcohol; reddish pink. 3. Oil of cassia; bright blue, second order.
5,000	Bluish white, second order	1. Water; pale yellow. 2. Alcohol; yellow, with tinge of orange. 3. Oil of cassia; yellowish pink, second order.
10,000	Fine blue, second order	1. Water; greenish white, second order. 2. Alcohol; yellowish white. 3. Oil of cassia; brilliant gamboge yellow.

Similar results were obtained with grooves impressed upon wax, so that it follows that more orders of colours, and higher tints, at a given incidence, are developed by diminishing the refractive power of the grooved surface. But one of the most interesting results in this table is the part in which the colours are entirely developed by the fluids applied to the surface; and hence if we had transparent fluids of much higher refractive powers, the colours would be produced when the intervals were much larger.

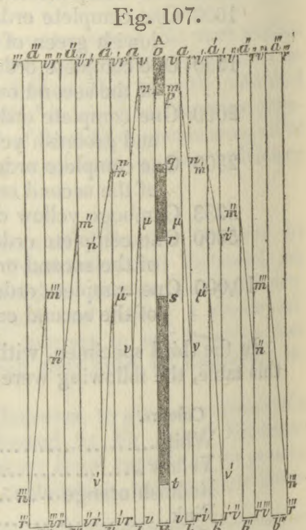
Similar phenomena were developed when the grooves were impressed on the fusible metal, on tin, and on isinglass. In those on isinglass, the new colours were seen also in the transmitted central image, and were extremely brilliant; but they were not decidedly complementary to those in the reflected image. The following were the colours of the reflected and transmitted image in isinglass, beginning from 90° of incidence:—

Colour of the reflected central image.	Colour of the same image, seen by transmission.
Yellow	Deep blue.
Orange	Paler blue.
Pink	Blue.
First limit of pink and blue	Blue.
Blue	Pink.
Green	Orange pink.
Yellow	Orange.
Orange	Yellow.
Pink	Yellow.
Second limit of pink and blue	Yellow.
Blue	Yellow.

Our author was now desirous of observing what took place in the prismatic images, when the colours appeared in the principal or central image.

Let AB, fig. 107, be the reflected image of a long rectangular aperture from the spaces between the grooves, and ab, $a'b'$, $a''b''$, $a'''b'''$, the prismatic images of it, vv, $v'v'$, &c. being the violet sides, and rr, $r'r'$, &c. the red sides of these spectra. Then in the

Fig. 107.



First spectrum ab, the *violet* rays are obliterated at m at an incidence of 74°, and the *red* rays at n at an incidence of 66°, the intermediate colours, blue, green, being obliterated at intermediate points between m and n, and at angles of incidence intermediate between 74° and 66°. In the

Second spectrum $a'b'$, the *violet* rays are obliterated at m' at an incidence of 66° 20′, and the *red* at n' at 54° 45′. In the

Third spectrum $a''b''$, the *violet* rays are obliterated at m'' at 57°, and the *red* at n'' at 41° 35′. And in the

Fourth spectrum $a'''b'''$, the *violet* rays are obliterated at m''' at 48°, and the *red* rays at n''' at 23° 30′.

Periodical Colours.

Another similar succession of obliterated tints takes place on all the prismatic images at a lesser incidence, as shown at $\mu\nu$, $\mu'\nu'$, the *violet* being obliterated at μ, and the *red* at ν, and the intermediate colours at intermediate points. In this second succession the line $\mu\nu$ begins and ends at the same angle of incidence, as the line $m''n''$ in the third prismatic image $a''b'$; and the line $\mu'\nu'$ on the second prismatic image corresponds with $m'''n'''$ on the fourth prismatic image.

Fig. 108.

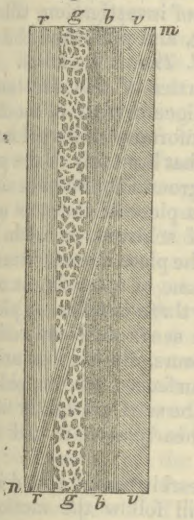


Fig. 109.

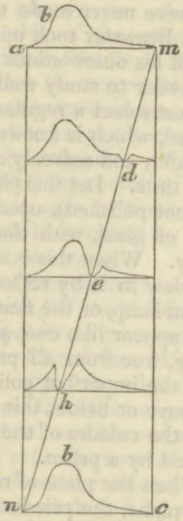


This singular obliteration of the colours is shown more clearly in fig. 108, where *rmvn* is a part of one of the prismatic images, *rr* the red space, *gg* the green space, *bb* the blue, and *vv* the violet space. The line of obliteration *mn* begins at *m*, the extreme violet being obliterated there, so that the curve of illumination *abm*, fig. 109, is just affected at one extremity *m*. The line advances into the spectrum, and at the point corresponding to *d*, fig. 109, a portion of the blue and violet is obliterated, as shown by the notch in the curve; at *e* a portion of the green and blue; at *h* a portion of the red and green, and at *n* the extreme red.

A similar obliteration of tints takes place on the ordinary image AB.

The first obliteration, viz. that of the violet, takes place at *o*, fig. 107, and that of the red at *p*; while the intermediate colours disappear at intermediate points. This first space of obliteration has no corresponding one at the same incidence in any of the prismatic images.

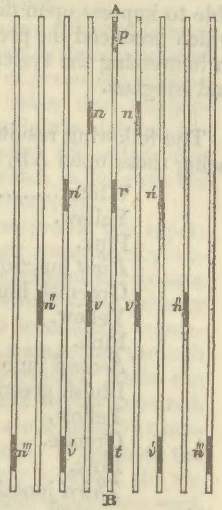
The second obliteration of the violet in AB takes place at *q*, and that of the red at *r*, and this corresponds in incidence with the obliterations $m'n'$, $m'n'$ on the second prismatic image.

The third obliteration of the violet takes place at *s*, and that of the red at *t*, and this corresponds in incidence with the four obliterations on the second and fourth prismatic images, viz. $\mu\nu$, $\mu'\nu'$, $m'''n'''$, $m'''n'''$.

In all these phenomena the points m, n, μ, ν, &c. are only the points of minimum intensity, or of maximum obliteration; for the tints never entirely disappear, and those obliterated at each line *mn* form an oblique spectrum containing all the prismatic colours.

The analysis of these curious and apparently complicated phenomena becomes very simple when they are examined under homogeneous illumination. The effect produced in red light is represented in fig. 110, where AB is the image of the rectangular aperture reflected from the faces *n* of the steel, and the four images on each side of it correspond with the prismatic images. All these nine images, however, consist of homogeneous red light, which is obliterated at the fifteen shaded rectangles, which are the minima of the new series of periodical colours which cross both the ordinary and the prismatic images. The centres p, r, t, n, ν, &c. of these rectangles correspond with the points marked with the same letters in fig. 107; and if we had drawn the same figure for violet light, the centres of the rectangles would have corresponded with o, q, s, m, μ, &c. in fig. 107. The rectangles should have been shaded off to represent the phenomena accurately, but the only object of the figure is to shew to the eye the position and relations of the minima of the periods.

Fig. 110.



If it should be practicable to remove a still greater portion of the faces *n*, the first minimum *p*, fig. 110, would commence at a greater angle of incidence; and other two rows of minima, namely, rows of five and six, would be found extending to the fifth and sixth prismatic images. The arrangement and succession of these is easily deducible from fig. 110, where the law of the phenomenon is obvious to the eye.

The following table contains the angles of incidence reckoned from the perpendicular at which these minima occur in the extreme rays.

Position of the minima in red light.

	Ord. Im.	1st Prism Im.	2d Prism Im.	3d Prism Im.	4th Prism Im.
First minima *p*...	76° 0′	66° 0′	55° 45′	41° 35′	23° 30′
Second minima *r*	55 45	41 35	23 30		
Third minima....	23 30				

Position of the minima in violet light.

	Ord. Im.	1st Prism Im.	2d Prism Im.	3d Prism Im.	4th Prism Im.
First minima	81° 30′	74°	66° 20′	57°	48°
Second minima...	66 20	57	48		
Third minima...	48				

When the steel with 1000 grooves is exposed to common light, and the incident ray is very near the perpendicular, the 5th, 6th, 7th, and 8th prismatic images are combined into a mass of whitish light, terminated externally by a black space. As the angle of incidence increases, the 6th, 7th, 8th, and 9th images are combined into this mass, then the 7th, 8th, 9th, and 10th images, and so on; the black space which terminates this mass receding from the axis or image AB, fig. 107, as the obliquity of the incident ray increases.

Having covered the steel plate with water and oil of cassia in succession, I found the angular distances of the black space to be as follows at the same incidence:—

Air..................................	12° 23′
Water................................	17 15
Oil of cassia........................	21 22

the sines of which are inversely as the indices of refraction of the fluids.

Phenomena analogous to those above described take place on the grooved surfaces of gold, silver, and calcareous spar, &c.

In order to study this subject under a more general aspect, I was desirous of examining the phenomena exhibited by grooved surfaces of different refractive powers. It was

Periodical Colours.

obviously impossible to procure systems of lines upon transparent bodies in which the grooves should have exactly the same distance and magnitude; but I conceived it practicable to impress upon different substances the very grooves which produced the preceding phenomena, and I succeeded in impressing the system of 1000 grooves upon tin, realgar, and isinglass.

The following results were obtained with *tin*, the colours being those upon AB, fig. 107 :—

White	90°	0′
Yellow.		
Pink.		
First junction of pink and blue	76	20
Greenish blue.		
Yellow.		
Pink.		
Second junction of pink and blue	57	40
Bluish green.		
Yellow.		
Orange.		
Pink.		
Third junction of pink and blue.		
First minimum of red	76°	
Second ———	61	

The following results were obtained with *realgar* :—

White	90°	0′
Yellow	80	
Pink	75	30
First junction of pink and blue	73	10
Blue	72	
Bluish green	70	15
Yellow	63	
Bright pink	54	
Second junction of pink and blue	47	
Bluish green	41	
Yellow	36	
Pink	32	
More and more pink.		
First minimum of red	72°	0′
Second ———	61	15

The following results were obtained with *isinglass*. The colours were generally the same as in the steel :—

The first limit of pink and blue was at	75°	45′
The blue of second order	73	45
The second limit of pink and blue was at	54	30

In these experiments the tin gave nearly the same results as the steel; but in the realgar and the isinglass similar tints were produced at a less angle of incidence than in the steel. The minima of the periods were exhibited very finely on the isinglass, and were produced at smaller angles of incidence.

In a specimen with 1000 grooves upon isinglass, the third pink, or that seen upon steel at 36°, was the highest; but after drying, the pink descended to yellow, and subsequently to green.

If the isinglass is removed from the steel when it is still soft, the edges of the grooves get rounded and lose their sharpness, and only one prismatic image is seen on each side of the ordinary image, as in mother-of-pearl.

The mass of white light is finely seen in the impressions taken upon tin, but never appears upon isinglass.

The prismatic colours seen on mother-of-pearl are exactly of the same kind as the prismatic images of grooved surfaces, with this difference, that a single prismatic image only is seen on each side of the common colourless image. The following account of these colours has been given by Sir David Brewster, who first analysed them, and discovered their communicability to wax, the fusible metals, &c.

Properties of mother-of-pearl.

Mother-of-pearl, which constitutes the interior lining of the shell of the pearl oyster, and of various other shells, has been long employed in the arts for the purposes of use and of ornament. Every one must have observed the play of prismatic tints, from which this substance derives much of its value as an ornament; but the nature and origin of these tints were never made the subject of investigation, till Sir David Brewster took up the subject, and published the results of his observations in the *Phil. Trans.* for 1814.

In order to study well the properties of this substance, we must select a regularly formed piece or plate of mother-of-pearl, which is known by the uniformity of its colour in day-light, and scarcely exhibits in that light any of the prismatic tints. Let this plate be now ground flat on both sides, (but not polished), upon a hone or a piece of slate, or upon a bit of glass, with the powder of schistus, or with fine emery. When this is done, hold the plate close to the eye, and view in it by reflexion the flame of a candle, or of an argand lamp, or the flame of two or three candles, so placed as to appear like one, and we shall see a dull and reddish image, free from all prismatic colours, its dulness arising from the imperfect polish of the surface. On one side of, or above or below, this image, will be seen a brighter image with the colours of the spectrum, nearly as if it had been formed by a prism.

When the plate of mother-of-pearl is turned round in its own plane, the prismatic image will follow the motion of the plate, and revolve round the common image, the *blue* rays being nearest the common image, and the *red* rays farthest from it. If the plate is so placed that the prismatic image is in the plane of reflexion, and between the common image and the observer, it will be found that the distance between the two images increases with the angle of incidence, being about 2° 7′ at an incidence not far from the perpendicular, and 9° 14′ at a very great obliquity. This distance between the images varies more rapidly when the plate is turned round 180° in azimuth, so that the common image is between the prismatic image and the observer; but in this case we cannot measure the angle accurately much beyond 60°, when it is nearly 4° 30′.

Beyond the prismatic image, and in the same line with it and the common image, will be observed a mass of coloured light, nearly as far beyond the prismatic image as the prismatic image is from the common image. The distance of this patch of coloured light varies according to a different law from that of the prismatic image, as the rays which form it have previously suffered refraction. This mass of light has a beautiful *crimson* colour at great angles of obliquity. At 37° of incidence it is *green*, and at less angles it has a *yellow* hue, approaching to *white*, and becomes very luminous. These colours become more brilliant when the plate is polished, and have an origin quite different from those of the prismatic image.[1]

Hitherto we have considered the phenomena only when the surface has that degree of polish which accompanies smooth grinding. If a greater degree of polish, however, is communicated to the plate, the common image becomes more brilliant, and *a new prismatic image starts up, diametrically opposite to the first prismatic image, and at the same distance from the common image.* This second prismatic image resembles in every respect the first. Its brilliancy increases with the polish, and when this polish is very high, the second prismatic image is nearly as bright as

[1] See *Phil. Trans.* 1836, p. 55.

the first, which has its brilliancy a little impaired by polishing. This second image is never accompanied, like the first, by a mass of coloured light. If the polish of the surface is removed by grinding, the second prismatic image vanishes, and the first resumes its primitive brilliancy.

When the preceding experiments are repeated on the opposite surface of the plate of mother-of-pearl, the same phenomena are observed, but in a *reverse* order, the first prismatic image and the mass of coloured light being now seen on the opposite side of the plate.

In examining the light transmitted through the mother-of-pearl, we shall perceive analogous phenomena. A coloured image will be seen on each side of the common image, having the same angular distance from it as those seen by reflexion, and resembling them in every particular; the blue light being nearest the common image, and the red light farthest from it. These two images, however, are generally fainter than those seen by reflexion. When the second prismatic image is extinguished by removing the polish, it is then the most brilliant when seen by transmission; and, in general, the image which is brightest by reflexion is faintest by transmission, and *vice versa*.

In measuring the angular distances of the prismatic image from the common image seen by reflexion, Sir David Brewster had occasion to fix the mother-of-pearl to a goniometer by means of a cement made of rosin and bees' wax. Upon removing it from the cement, by insinuating the edge of a knife, and making it spring off, the plate of mother-of-pearl left a clean impression of its own surface; and he was surprised to observe, that the cement had actually received the property of producing the colours which were exhibited by the mother-of-pearl. This was at first attributed by our author, and others who saw the experiments, to a very thin film of mother-of-pearl detached from the plate, and left upon the cement; but subsequent experiments convinced him that the mother-of-pearl communicated to the cement its own properties.

In order to shew this remarkable property to advantage, the plate of mother-of-pearl should be fixed to a handle like a seal, and its surface carefully cleaned. The sealing-wax should be black, and the impression taken by an impulse of the plate against the black sealing-wax, when rendered as fluid as possible by heat.

The properties of mother-of-pearl may also be communicated in this way to *balsam of tolu*, *gum-arabic*, *gold leaf* placed upon wax, *tinfoil*, the *fusible metal* composed of bismuth and mercury, and to *lead*, by hard pressure, or the blow of a hammer. When the impression is first made upon the *fusible metal*, the play of colours is singularly fine; but the metallic surface soon loses its polish, and the colours gradually decay.

If dissolved *isinglass* or *gum-arabic*, &c., are placed upon the plate of mother-of-pearl, and allowed to harden upon it, they will exhibit in the most splendid manner the colours of the substance; or if we indurate these gums between two plates of mother-of-pearl, we shall have transparent films, exhibiting on both sides the play of the prismatic tints.

In order to show that in these cases no part of the mother-of-pearl is left on the surface, Sir David Brewster plunged a piece of wax, with the impression, into nitric acid, which would instantly have destroyed the carbonate of lime, of which the mother-of-pearl is chiefly composed, but it had no effect on the colorific property of the surface. In soft cements, made of bees' wax and rosin, the slightest degree of heat destroys the superficial configuration, by which the colour is produced. In *sealing-wax*, *isinglass*, *gum-arabic*, and *realgar*, a much greater heat is necessary to destroy it; but in *tinfoil* and *lead*, its destruction can only be effected by the temperature at which they cease to become solid.

If we now examine the prismatic images *reflected* from the wax which has received the impression from an unpolished piece of mother-of-pearl, we shall find that the single prismatic image which is thus produced is on the *right hand* of the common image, whereas it is on the *left hand* of the common image in the mother-of-pearl itself.

At different angles of incidence, the two coloured images formed by the wax, follow the same laws as those produced by the mother-of-pearl; but the mass of *green* and *crimson* tints never appears in the impressions taken from mother-of-pearl, because they are produced by light which has penetrated the mother-of-pearl, and has after refraction been reflected from one or more thin plates which lie between the strata of which the mother-of-pearl is composed.

In communicating to *isinglass* or *gum-arabic* the superficial structure of mother-of-pearl, their transparency enables us to observe the phenomena of the transmitted colours. The two prismatic images were both visible—the primary one being remarkably brilliant, and the second one scarcely perceptible; but when the light was transmitted through the gum, the primary image was nearly extinct, while the secondary one was unusually brilliant and highly coloured, far surpassing in splendour those which are formed by transmission through the mother-of-pearl itself. When both the surfaces of isinglass or gum-arabic have received the superficial structure of mother-of-pearl, four images are seen. The *transmitted* colours are more brilliant in *gum-arabic* than in *balsam of tolu*, as the latter reflects more light; but the prismatic images have the same degree of colour or dispersion when formed by *isinglass* or *gum-arabic*, as when they are formed upon *metallic* surfaces.

From these facts it is obvious that the principal phenomena of mother-of-pearl have their origin in a particular configuration of its surface. By the use of the microscope Sir David Brewster discovered in every specimen of mother-of-pearl that gave the prismatic images, a grooved structure upon its surface, resembling the delicate texture of the skin at the tip of an infant's finger, or the lines which mark out islands and coasts upon a map.

In many specimens of mother-of-pearl, the grooves are parallel, but they are often arranged in all possible directions like the veins of agate, and in this case the common reflected image is surrounded with a number of prismatic images sometimes arranged in a circular or oval form, more or less regular. Sometimes the spaces between the grooves, or rather the edges of the strata of the shell, can be seen by the naked eye, or by a magnifying power of six or eight times, in which case the prismatic images are less highly coloured, having whitish light in their centre, and are placed close to the common image. At other parts of the same plate, more than 3000 grooves may be counted in an inch, and in some places they cannot be detected by ordinary magnifying powers. When the spaces between the grooves are wide, a new groove often begins, and there is often a sudden change from a series of wide grooves to a series of close ones. When the mother-of-pearl is scratched, the bottom and sides of the scratches are grooved exactly like the parts that are polished.

The direction of the grooves is always at right angles to the line joining the common image and the prismatic image. Had the grooved structure appeared only upon its external surface, the phenomena and the communicable colours would have disappeared when the surface was ground down; but the surprising part of the phenomenon is, that if we grind down the external surface with the finest powders, and polish it to the utmost degree, we never can grind out the grooved structure, and replace it by a flat surface. The edges of the shell break off by the action of the finest powders, so that the termination of one stratum cannot pass into the subjacent stratum without being separated by a distinct line or edge, formed by the fracture of its thin marginal parts. As all the strata have thus a prismatic termination, the mass of green and crimson light is reflect-

Periodical Colours.

ed from near the edge of the surface upon which the superincumbent stratum lies.

Sir John Herschel discovered in very thin plates of mother-of-pearl a pair of nebulous prismatic images more distant from the central image than the two prismatic ones above described, and also a pair of fainter nebulous images, the line joining which is perpendicular to the line joining the first pair. He saw them by looking through thin pieces between the 70th and 300th of an inch thick. They are produced by a veined structure, in which there were 3700 veins in an inch. They cross the common grooves at all angles, and are parallel to the plane passing through the centres of the two systems of the coloured rings.

The spurious discs of stars first noticed by Sir William Herschel, have been justly considered as arising from diffraction, and have been described as supplementary facts to those discovered by Fraunhofer, in Sir John Herschel's *Treatise on Light;* and we believe every thing distinctly known on the subject, is due to the latter. A good telescope with a small power, shews fixed stars as a bright mass of light with some extraneous rays. A magnifying power of from 200 to 400, in favourable weather, exhibits the star as a well defined disc surrounded by several alternately dark and bright equidistant rings slightly coloured at their margin. These rings are best seen in refracting telescopes, with which the central disc is larger than in reflectors.

In applying apertures of various figures to the mirrors and object-glasses of telescopes, Sir John Herschel obtained the following results:

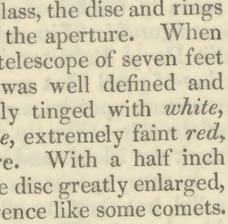
Effects produced by apertures of various shapes.

With the largest circular diaphragm, either near to, or distant from the spectrum or object-glass, the disc and rings increase inversely as the diameter of the aperture. When the aperture was only one inch in a telescope of seven feet in focal length, the disc of the star was well defined and surrounded with one ring only faintly tinged with *white,* faint *red, black,* very faint *blue, white,* extremely faint *red,* and *black,* reckoning from the centre. With a half inch aperture, the rings were invisible, the disc greatly enlarged, the light shading off to the circumference like some comets. This is shewn in fig. 11, Plate CCCLXXXII.

Plate CCCLXXXII. Figs. 11.–22.

With annular apertures the phenomena were highly beautiful. When the outside of the annulus was three inches and the inside one and a quarter, *Capella* appeared as in fig. 12, and the double star *Castor* as in fig. 13. When the breadth of the annular aperture is diminished, the disc and the breadth of the rings also diminish, while the number of visible rings increases. The appearance of Capella with annular apertures of 5·5 inches exterior, 5·5 interior, of 0·7 exterior, of 0·2 interior, and of 2·2 exterior, of 2·0 interior, is represented in figs. 14, 15, and 16. In the last figure the disc was reduced to a point, and the rings were so numerous and close that they could scarcely be counted. When the breadth of this annulus was reduced one-half, the rings were invisible.

Fig. 111.



When two annuli, as shewn in the annexed figure, were used, large halos or rings were seen by Sir John Herschel, as in fig. 17, plate CCCLXXXI.

Fig. 17

With an aperture of the shape of an equilateral triangle, or the opening between two concentric equilateral triangles, the figure was that shewn in fig. 18, in which the small central disc was extremely bright, and the field of the telescope black.

When the preceding figure is seen with the telescope out of focus, it changes into fig. 19.

When three circular apertures are placed at the angles of an equilateral triangle, the effect shewn in fig. 20, is produced.

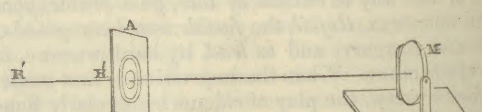
When three equal and similar annular apertures were arranged in the same manner, the effect was as in fig. 12. When this was thrown out of focus, it had the appearance in fig. 21; when brought better into focus, it changed into fig. 22; and when in focus, into fig. 12.[1]

SECT. IV.—*On the Colours of concave Mirrors or thick Plates.*

Colours of thick plates

The colours produced by thick plates were discovered by Sir Isaac Newton, who has given the following account of them.[1] "There is no glass or speculum however well so ever polished but besides the light which it refracts or reflects regularly, scatters every way irregularly a faint light by means of which the polished surface, when illuminated in a dark room by a beam of the sun's light, may be easily seen in all positions of the eye. There are certain phenomena of this scattered light, which, when I first observed them, seemed very strange and surprising to me. The sun shining into my darkened chamber through a hole in the shutter AB, one-third of an inch wide, I let the intromitted beam of light RR fall perpendicularly upon a glass speculum M, ground concave on one side, and convex on the other, to a sphere of five feet and eleven inches radius, and quick-silvered over on the convex side. And holding a white opake chart, or a quire of paper, at the centre of the sphere to which the speculum was ground, that is, at the distance of about five feet and eleven inches from the speculum, in such a manner that the beam of light might pass through a little hole made in the middle of the chart to the speculum, and thence be reflected back to the same hole: I observed upon the chart four or five concentric irises or rings of colours like rainbows, after the manner that those in the fourth and following observations of the first part of this third book encompassed the black spot, but yet larger and fainter than those. If the distance of the chart from the speculum was much greater or much less than that of six feet, the rings became dilute and vanished,

Fig. 112.



The colours of these rainbows succeeded one another from the centre outwards, in the same form and order with those transmitted through the two object glasses.

Measuring the diameters of these rings upon the chart, I found them also in the same proportion to one another with the rings between the two object glasses. For the diameters of the four first of the bright rings measured between the brightest parts of their orbits at the distance of six feet from the speculum, were $1\frac{11}{16}$, $2\frac{3}{8}$, $2\frac{11}{12}$, $3\frac{3}{8}$ inches, whose squares are in arithmetical progression of the numbers 1, 2, 3, 4. If the white circular spot in the middle be reckoned amongst the rings, and its central light, where it seems to be most luminous, be put equipollent to an infinitely little ring; the squares of the diameter of the rings will be in the progression 0, 1, 2, 3, 4, &c. I measured also the diameters of the dark circles between these luminous ones,

[1] Sir John Herschel's *Treatise on Light,* § 769, &c. in which the reader will find the subject more fully treated.

[2] This account is abridged from Newton's Optics, book ii. part iv. p. 264.

riodical olours.

and found their squares in the progression of the numbers $\frac{1}{2}$, $1\frac{1}{2}$, $3\frac{1}{3}$, &c. The diameters of the first four at the distance of six feet from the speculum, being $1\frac{3}{16}$, $2\frac{1}{16}$, $2\frac{2}{3}$, $4\frac{5}{20}$ inches. If the distance of the chart from the speculum was increased or diminished, the diameters of the circles were increased or diminished proportionally.

"When the beam of the sun's light was reflected back from the speculum, not directly to the hole in the window, but to a place a little distant from it, the common centre of that spot, and of all the rings of colours fell in the middle way between the beam of the incident light, and the beam of the reflected light, and by consequence in the centre of the spherical concavity of the speculum, whenever the chart on which the rings of colours fell was placed at that centre. And as the beam of reflected light, by inclining the speculum, receded more and more from the beam of incident light, and from the common centre of the coloured rings between them these rings grew bigger and bigger, and so also did the white round spot, and new rings of colours emerged successively out of their common centre, and the white spot became a white ring encompassing them; and the incident and reflected beams of light always fell upon the opposite parts of this white ring, illuminating its perimeter like two mock suns in the opposite parts of an iris. * *

"The colours of the new rings were in a contrary order to those of the former, and arose after this manner. The white round spot of light in the middle of the rings continued white to the centre, till the distance of the incident and reflected beams at the chart was about $\frac{7}{8}$ parts of an inch, and then it began to grow dark in the middle. And when that distance was about $1\frac{3}{8}$ of an inch, the white spot was become a ring encompassing a dark second spot which in the middle inclined to violet and indigo. * *

"When the distance between the incident and reflected beams of light became a little bigger, there emerged out of the middle of the dark spot after the indigo a blue, and then out of that blue a pale green, and soon after a yellow and red. * *

"When the distance of the two beams of light at the chart was a little more increased, there emerged out of the middle in order after the red, a purple, a blue, a green, a yellow, and a red inclining much to purple." By the successive development of these colours, rings are formed within the white circle till they become very dilute and vanished while the white ring, and one or two on each side of it, continued visible; and these also vanished when the distance between the two beams of light was still more increased.

"These are the phenomena," says Sir Isaac, "of thick convexo-concave plates of glass, which are everywhere of the same thickness. There are yet other phenomena when these plates are a little thicker on one side than on the other, and others when the plates are more or less concave than convex, or plano-convex, or double convex. For in all these cases the plates make rings of colours, but after various manners."

The Duke de Chaulnes[1] observed colours analogous to those of thin plates, when the surface of a mirror was covered with a thin film of milk after it was dry, or with a screen of gauze or muslin placed at a small distance in front of the mirror. Sir Wm. Herschel[2] has given an account of an interesting experiment in which, by dispersing hair-powder in the air before a metallic speculum on which a beam of light is incident, and receiving the reflected beam on a screen, fine rings of colour are produced; or an analogous phenomena may be seen by scattering hair-powder on the face of a common looking-glass.[3]

Sir David Brewster has remarked,[4] that the method which he has found the most simple for exhibiting these colours, is to place the eye immediately behind a small flame, from a minute wick fed with oil or wax, so that we can examine them even at a perpendicular incidence. The colours of thick plates may be seen even with a common candle held before the eye at the distance of ten or twelve feet from a common pane of crown glass in a window that has accumulated a little fine dust upon its surface, or that has on its surface a deposition of fine moisture. Under these circumstances they are so very bright, that they may be seen even when the pane of glass is clean.

Periodical Colours.

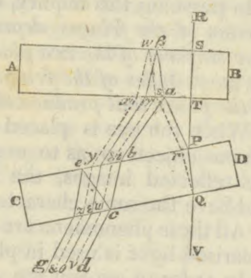
SECT. V.—*On the Colours produced by Double Plates of Glass of equal thickness.*

Colours of double plates of equal thickness.

In 1815, Sir David Brewster published in the Edinburgh Transactions[5] "An account of a new species of coloured fringes produced by the reflection of light between two plates of parallel glass of equal thickness."

In these experiments he cut the plates of glass AB, CD, fig. 112, out of the same piece, and having placed between them a bit of soft bees' wax, he pressed them together till they were at the distance of nearly the tenth of an inch, and slightly inclined to each other as in the figure, till one or more of the reflected images of a circular luminous disc seen in the direction VR by an eye at V, were reflected from the bright and direct image formed by transmitted light. When this was done the reflected image was crossed with about fifteen or sixteen beautiful parallel fringes. The three central fringes consist of blackish and whitish stripes, and the exterior ones of brilliant stripes of red and green light; and the central fringes have the same appearance in relation to the external fringes, as the internal have to the external rings formed by thin plates. If the two plates of glass are turned round in a plane at right angles to the incident ray, the reflected images will move round the bright image, and the parallel fringes will always preserve a direction at right angles to a line joining the centres of the bright and reflected images. Hence it follows, *that the direction of the fringes is always parallel to the common section of the four reflecting surfaces, which exercise an action upon the incident light.*

Fig. 113.



The position of the plates remaining as before, let the inclination of the plates, or, what is the same thing, the distance of the bright and the reflected image, be varied by a gentle motion of one of the plates, *the coloured fringes will be found to increase in breadth as the inclination of the plates is diminished, and to diminish as the inclination of the plates is increased.*

If the light of the circular object, instead of falling perpendicularly upon the plates, is incident at different obliquities, so that the plane of incidence is *at right angles to the common section of the plates,* no fringes are visible across any of the images. But if the plane of incidence is *parallel to the common section of the plates,* the reflected images increase in brightness with the obliquity of incidence, and the coloured fringes become more vivid. When

Periodical Colours.

the angle of incidence increases from 0° to 90°, the images that have suffered the greatest number of reflections are crossed by other fringes, inclined to them at a small angle. At an angle of about 44°, the image formed by four reflexions is covered with interfering fringes; but it is not till the angle of incidence is greater, that this is distinctly seen on the image formed by two reflexions.

Hitherto he had observed no fringes upon the first or bright image, which is composed of light that has not suffered reflexion from the second plate of glass. By concealing, however, the bright light of the first image, so as to perceive the image formed by a *second* reflexion, within the first plate, and by viewing this image through a small aperture, which he found of great service in giving distinctness to all the phenomena, he observed fringes across the first image, far surpassing in precision of outline, and in richness of colouring, every analogous phenomenon which he had seen. When these fringes were concealed, he also observed other fringes on the image immediately behind them, and formed by a *third* reflexion, from the interior of the first plate. He concealed the second image, upon which the fringes were extremely bright, and very faint stripes were seen upon the one immediately behind it.

In examining these phenomena a little more attentively, he observed that the size of the fringes in the first image varied with the distance of the eye from the plates, while those on the second and fourth image diminished with that distance.

In pursuing this inquiry, our author found *that the production of the fringes depends upon the action of all the four surfaces of the two plates of parallel glass; and that the magnitudes of the fringes are inversely as the thickness of the plates that produce them at a given inclination.*

When the eye is placed between the plates and the luminous object, so as to see the *first, third, fifth, seventh,* &c. reflected images, the coloured fringes are also seen, and have the same character as those already described.

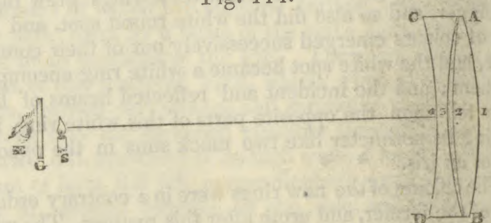
All these phenomena are seen without any variation when polarised light is used in place of common light.

In order to explain the changes which the light undergoes in its passage through the plates of glass, let AB, CD, fig. 113, be a section of two plates at right angles to the common section of their surfaces, and let RS be a ray of light incident nearly in a vertical direction. This ray, after passing through the first plate AB, will suffer a small refraction at P and Q, and emerge in the direction QV parallel to RS. At the point P, in the second plate CD, the ray TP will be reflected to a, again reflected to b, and, after suffering a refraction at b and c, will emerge in the direction cd, forming with RV an angle equal to twice the inclination of the plates. A portion of the reflected ray Pa, will enter the first plate at a, and having suffered reflexion and refraction at β, the reflected portion $\beta\gamma$ will reach the eye at θ. The ray P $a\ b\ c$ will likewise suffer a reflection at c and e, and will reach the eye at g. In like manner, a part of the ray PQ will be reflected at Q, and move in the direction Q$r\,s\,t\,u\,v$, and another part of it in the direction $s\,w\,x\,y\,z$, and these rays will suffer several other reflexions; but the images which they form will be so faint, that the eye will not be capable of perceiving them. When the observer, therefore, looks at a luminous body, in the direction SR, through the glass plates, he will perceive two images, one of which is a bright image, seen by the transmitted light QV, and the other is a faint image, seen principally by the reflected light P $a\ b\ c\ d$ and composed of several images, formed by the pencils $c\,d$, $u\,v$, $\epsilon\,\theta$, z &, and $e\,g$. The bright image is not crossed by coloured fringes, but the fringes appear distinctly upon the other image; and the light by which these fringes are formed, has suffered two reflexions from the exterior surfaces, and two refractions at the interior surfaces of the plates."

Dr. Thomas Young, in the article CHROMATICS in this work,[1] has given an explanation of these phenomena upon the principles of interference, and Sir John Herschel has shewn by an interesting analysis of them, that they are well fitted for illustrating the laws of this class of phenomena, and may be readily explained by interference.[2]

When two or three plates are combined, as in the form of concave and convex lenses, and are combined as in the double and triple achromatic object-glass, a series of beautiful systems of rings are developed. The method of observing these rings, and by which Sir David Brewster discovered them, is shewn in fig. 114, where ABCD is the section of the object-

Fig. 114.



glass, including a meniscus of air. A small flame S, is placed about four or five inches from the object-glass, and a small screen G, is interposed between the flame and the eye at E, which is kept as close to S as possible. The distance of the object-glass is then varied, till the inverted greenish coloured flame reflected interiorly from the concave surface A 1 B, seems to cover the whole area of the object-glass. When this takes place, the rings may, by a slight change in the position of the object-glass, or by screening the image formed by the reflection from A and B, be seen in the distinctest manner over the expanded but enfeebled image formed by a second reflexion from the same surface.

When the flame is small, and the eye sees it projected against the centre of the object-glass, the rings form a concentric system, as shewn in fig. 23, Plate CCCLXXXIII, approaching closer and closer to each other, towards the circumference of the lens. Two of these rings *mmmm, n, n, n, n,* were distinguished from the rest by their darkness, and by the whiteness of the light between them; and they are the bounding lines of four systems of fringes, into which the general system subdivides itself by oblique reflection; in order to see this change, incline the object-glass so that the point A is farther from the eye than B, and so that the eye may receive the obliquely reflected rays from every point of the surface A and B. At a slight deviation from the perpendicular, the rings become smaller and closer on the side A, and larger and more separated on the side B. At greater incidences the inner ring *aa*, fig. 23, contracts into an irregular crescent *aa*, fig. 24. The second and third rings *bbcc*, fig. 23, do the same, as shewn at *bbcc*, fig. 24; and at a greater incidence the dark ring *nn*, fig. 23, assumes a similar form *nnnn*, fig. 24, and forms the boundary of the *remote central system, ncbaabcn.* In like manner the lower part of the ring *nn*, fig. 23, has enclosed a smaller but similar system of rings, which are shewn at *n'n'n'n'*, and may be called the *near central system.* While these changes are going on, the rings without *nn*, fig. 23, are undergoing analogous, though opposite, inflexions. The outermost, *ddd*, fig. 23, divides itself into two unequal portions, which run out into the circumference at the points

[1] Vol. vi. p. 636, sect. vi.

Periodical Colours.

$dd\acute{d}d'$, fig. 24. Then the next ring, viz. the dark one, m, m, m, m, forming the boundary of the *remote external system*, m, m, m, A, and of the *near central system* m', m', m', B. The four groups of rings thus developed, assume at greater incidences the character shewn in fig. 25, but they are not seen all at once; and in tracing their form it is necessary to cause the image on which they are produced to be reflected successively from different parts of the lens. The rings are so closely packed together, at a distance from the white centres $x'x$, to which they are all related, that it is extremely difficult to perceive them in the present object-glass. At a still greater angle of incidence, the rays close in upon the centres $x'x$, and become exceedingly close and nearer as the points $x'x$ approach to the circumference of the lens, and the rays become brighter from the increase of the light at greater obliquities.

Plate CCCLXXXIII. Fig. 24. Fig. 25.

In some double object-glasses the rays can only be seen by looking through the convex crown glass lens. In one object-glass the four bounding fringes at xx, fig. 25, united and formed a black cross, as shewn in fig. 26. From a series of experiments Sir David Brewster has found that in the object-glass shewn in fig. 113, the action of the two surfaces 1, 2 of the convex lens AB, and the inner surface 3 of the concave one CD, are necessary to the production of these fringes, and hence he concludes that the rings arise from the interference of two pencils of light, one of which has suffered *three* reflections within the convex lens AB, and has passed *four* times through its thickness, with another pencil which has suffered *two* reflexions within the convex lens, and *one* reflexion from the inner surface of the concave lens, and has passed *four* times through the thickness of the convex lens, and *twice* through the thickness of the meniscus of air.

Fig. 26.

In a triple object-glass, which gave a system of rings similar to that in fig. 26, they were covered with *another system of very minute fringes*, parallel to one another, and to the line joining the centres x and x.[1]

Sect. VI.—*On the Colours of Double Plates of Glass of Unequal Thickness, and other Analogous Phenomena.*

Colours of Double Plates of Equal Thickness.

Mr. W. Nicholson observed the colours of thick plates in the glasses employed for the sights of sextants, and he considered them analogous to those of thin plates. They have been ascribed, however, by Dr. Young,[2] "to the rays twice reflected in the second plate only."

Knox.

Mr. Knox of Belfast[3] has described some interesting phenomena already briefly noticed by Dr. Young, in the article Chromatics. Having formed a system of the rings of thin plates, by placing a convex lens on a piece of silvered glass, he observed the common system of reflected rings, and also the transmitted system reflected to his eye by the silvered glass. This is shewn in fig. 27, Plate CCCLXXXIII. where A and B are the two systems; but he was surprised to observe between them a system of parallel fringes CD EF, passing through the intersection of the two circular systems. These fringes were equal in number to the number of the rings in A and B. They were equidistant, reached the edge of the lens on both sides, and were formed at right angles to the direction of the light, and to a line forming the centres of the systems A and B.

Fig. 27.

Our author then tried the effect of combining two primary systems of reflected rings in the same manner. With this view he placed a double-convex lens about thirty-six inches in focal length, on a piece of plate glass, with its under side painted black, and upon the lens he placed a piece of plate glass. By these means two sets of primary rings were produced, whose relative positions could be altered at pleasure. By using the shadow of a black card, he found that, instead of parallel fringes, as in fig. 27, he had a new species of rings of a circular form, from two to three times the diameter of the primary rings from which they originated. These rings passed, as before, through the intersections of the primary ones; and the ring which divided the two classes passed through a point, whose distance from the centre of each primary set were in proportion to their longest diameters.

These rings, which Mr. Knox calls *intersectionary* ones, may be made to vary infinitely in their dimensions, according as the diameters of the primary sets differ more or less, being least where that difference is greatest, and increasing in size as the two primary sets approach to equality, until at last they become straight lines, when the two primary sets are equal. The dimensions of the intersectionary rings will also, as Mr. Knox remarks, *ceteris paribus*, diminish as the two primary sets approach, and increase as they recede from one another.

As these intersectionary rings are almost always accompanied by a second, and sometimes by a third set of equal or unequal dimensions, Mr. Knox supposes that they may be produced by primary sets, combined with either transmitted or reflected sets, provided the two between which they are formed are of unequal dimensions.

Considering the intersectionary fringes as diagonals to the angles at which they were formed, Mr. Knox conjectured that if he could form rectilineal fringes by flat plates, and combine them at different angles, he would produce a third or diagonal set placed between the other two. He accordingly took a pair of slips of glass, and by applying two of their ends together, and using some friction, and a considerable degree of pressure, he formed a fine set of rectilineal fringes. By applying a third slip of glass longitudinally to the upper one of the first two, he formed a similar set of rectilineal fringes at right angles to the first; and he immediately observed the diagonal fringes, which he had anticipated, appear in the angle between the two primary sets, as shewn in fig. 28, where B and C are the primary fringes, and D the intersectionary set, divided into two classes, as shewn by the dotted line. By forming the second set of fringes at different angles with the first, the central band of the intersectionary fringes always bisected the angle. It is a curious circumstance, that though the diagonal fringes are formed by the crossing of the two primary sets, yet they never appear at the opposite angle A, nor could they be made to appear in any angle formed by primary fringes, unless these fringes were so disposed as to have their red sides turned towards each other.

Plate CCCLXXXIII. Fig. 28.

Dr. Young has given an explanation of these curious phenomena in the article Chromatics,[4] to which we must refer the reader.

Dr. Young

Mr. Henry Fox Talbot upon superposing two films of blown glass and viewing through them a homogeneous yellow flame, and even the light of the sky, observed bright and dark stripes, or coloured bands and fringes, which were not produced by either of them separately. These phenomena, as Sir John Herschel remarks, are obviously referable to the same principle as the fringes discovered by Sir David Brewster, "the interference taking place here between rays respectively twice reflected within the upper lamina, and once reflected at the upper surface of the lower lamina, or else between rays, one of which is thrice reflected in the mode represented by $AaB'a'B'aA$, and the other in that represented by $AaB'aA'a'A$, the interval between the glasses being supposed to be exactly equal to the

Mr. Fox Talbot.

Periodical Colours.

thickness of the upper one in both cases, a condition which is sure to obtain somewhere when the laminæ are curved."[1]

Sect. VII.—*On the Colours of Fibres formed by Reflexion and Transmission.*

Colours of fibres.

Every person must have observed the fine thread or line of the spider's web glittering with the brightest colours, when the light of the sun is reflected from it to the eye. By examining these colours attentively, they are found to vary with the angle of incidence. The only attempt that we know of to explain this phenomenon, that deserves notice, is that of Sir John Herschel:—"These colours," says he, "may arise either from a similar cause, (namely, that which produces colour in a single scratch or fissure, or the interference of light reflected from its opposite edges,) or from the thread itself as spun by the animal, consisting of several agglutinated together, and thus presenting not a cylindrical but a furrowed surface." That the structure thus assumed would produce colours cannot be doubted, but they would be the colours of grooved surfaces such as we have already described, which we conceive to be exceedingly different from those of the spider's line.

It appears from a preceding section, that when a reflecting surface has its breadth reduced to an extreme degree of narrowness, whether it be a metallic or a transparent one, it is no longer capable of reflecting white light, but decomposes it in the manner already described, the coloured bands being transverse to the direction of the reflecting line. Sir David Brewster has therefore applied this new property of reflecting surfaces to account for the colour of the spider's line, which presents analogous phenomena, and which from its extreme minuteness, must necessarily decompose white light. If this is not the true cause of the phenomenon, it will not be easy to obtain any rational explanation from the doctrine of interference, without taking for granted the existence of a structure of a very peculiar kind.

On the Colours of Fibres by transmitted Light.

If we take a number of fibres of wool, and fix them in parallel directions, as in Fraunhofer's gratings, they would of course produce parallel spectra or coloured bands similar to those already described. If we take a mass of the same wool, in which the fibres have every possible direction, they will then exhibit spectra or fringes lying in every possible direction, or circular ones. As both these results would be equally obtained, if the fibres were cut down into particles as long as they are broad, we should have parallel fringes when the particles are arranged in straight lines, and circular ones when the particles are scattered like dust upon a plate of glass in all directions. Hence fibres of minute particles will produce circular fringes, which increase in diameter as the particles are smaller in diameter.

When we therefore look at a candle placed at a little distance, through wool, or cotton, or vapour lying upon glass, or diluted blood, or milk, or the seed and farina of plants, &c. &c., we observe round the image of the candle a light area terminating in a *dark reddish* margin. This is followed by a ring of *bluish green* light, and then a *red* ring, and when the fibres or particles have an uniform size, the green and red rings are frequently repeated. It is to Dr. Young that we owe the discovery that the diameter of these rings is always the same when the size of the particles or fibres is uniform and equal, and that they vary inversely as the size of the fibres or particles. On this principle he constructed his *eriometer* for measuring the diameter of minute particles and fibres, such as *wool*, &c. It is composed of a plate of brass, or copper, or even card, with an aperture in the centre about the fortieth of an inch in diameter, and surrounded by a circle of perforations about half an inch in diameter, the number of perforations in the circle being about ten or twelve, and as minute as possible. When the instrument is constructed on such a small scale, the eye requires the aid of a lens. The wool, or plate of particles, are then attached to the end of a slider, and when the light of an argand lamp, or two or three candles placed in a line, so as to unite their flames, is transmitted through the wool or particles, the slider is drawn out till the first *dark red* coloured circle coincides with the circle of particles, and the index then shews on the scale upon the slider the number which indicates the size of the fibres or particles. The basis of this scale, rather an imperfect one, Dr. Young took from Dr. Wollaston's measure of the magnitude of the seeds of the *puff ball* or *Lycoperdon bovista*, which he found to be the 8500ths of an inch in diameter. Dr. Young found the rings formed by these minute seeds to be three-and-a-half on the scale of his instrument, and hence he assumes the *thirty thousandth* part of an inch, (more accurately the 29750th), as the value of an unit on his scale. The following results were obtained by Dr. Young:—

Dr. Young's eriometer.

Table of the diameter of Fibres and minute particles.

Milk diluted, very indistinct, about	3
Lycoperdon bovista, dust of, very distinct	3½
Blood of a bullock, from beef	4½
Human blood, diluted with water	5
Smut of barley (male ear)	6½
Blood of a mare	6½
Human blood diluted with water after standing five days	6½
Blood recently diluted with serum, only	8
Pus	7½
Silk, very irregular	12
Wool of the beaver, jointed, very uniform	13
Angola wool, about	14
Vigonia wool	15
Siberian hare's wool, Scotch hare's wool, foreign coney wool, yellow rabbit's wool, about	15½
Mole's fur	16
Skate's blood	16
British coney wool, American rabbit's wool, about	16½
Saxon wool, a few fine fibres	17
Buffalo's wool	18
Wool of the mountain sheep, *ovis montana*	18
Seal wool, finest, mixed, about	18½
Shawl wool	18 or 19
Goat's wool	19
Cotton, very unequal	19
Peruvian wool, mixed, the finest locks	20
Welch wool, a small lock of	20
Saxon wool	23 or 24
Wool of an Escurial ram	23 to 24
Southdown wool	24½
Lioneza wool, 24 to 29	generally 25
Paular wool, 24 to 29	generally 25½
Alpacca wool, about	26
Laurestinus, farina of	26
Ryeland merino wool	27
Merino Southdown wool	28
Lycopodium seed, beautifully distinct	32
Southdown ewe wool	39
Coarse wool, Sussex	46
Coarse wool, from same, worsted	60

The diameter of the fibres or particles in the preceding table may be obtained in parts of an inch, by dividing the $\frac{1}{30,000}$ of an inch by the numbers opposite them. The diameter of the particles of the human blood will be

[1] *Treatise on Light*, § 693. See also *Biot, Traité de Physique*, tom. iv. p. 246.

riodical olours. — Periodical Colours.

$\frac{1}{30,000}$ divided by 5, or the 6000th part of an inch. Dr. Young has ingeniously observed, that if we square the number belonging to the pound of wool, and substract 325, the remainder will be nearly the number of pounds of wool that are worth 100 guineas. In the case of good Lioneza wool for example, whose number is 25, we shall have $25 \times 25 - 325 = 300$ for 100 guineas, or seven shillings per pound.[1]

In experiments of this kind it would be better to express the magnitude of the first ring in parts of the radius, or by the angle which the whole ring subtends at the eye. Those who have any of Mr. Barton's scales, with the number of lines in an inch marked, can easily compare the diameter of the first ring produced either by fibres or particles, with the distance of the red spaces in the two first prismatic images; and by the rule of proportion he will find the magnitude of the fibres or particles.

Sect. VIII.—*On the colours of mixed plates.*

ours of ed es.

eas.

The phenomena of colour observed by M. Mazeas, when he pressed between two glasses, suet, Spanish wax, resin, common wax, and the sediment of urine, are *clearly those of mixed plates*, though they have not hitherto been recognised as such. He put between his glass plates a little ball of suet about one-fourth of a line in diameter, and pressed it between the two surfaces, warming them at the same time in order to disperse the suet. He then rubbed them violently together in a circular manner, and was surprised at looking at a candle through them to see it surrounded with two or three concentric rings, very broad, and with very lively and delicate colours, namely, a red inclining to yellow, and a *green* like that of an emerald. By continuing the friction, the rings assumed the colours of *blue*, *yellow*, and *violet*, especially when he looked through the glasses on bodies directly opposed to the sun.

M. Mazeas[2] shews very clearly that these were not the colours of thin plates on account of the distance between the glasses, and also because the colours disappeared by melting the suet, but a new species of colours which he tried in vain to explain.

ur.

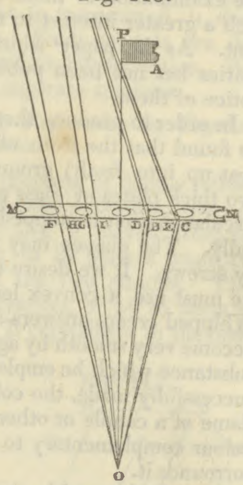
M. Dutour[3] repeated and varied the experiments of Mazeas, but did not succeed in explaining them.

oung.

Dr. Thomas Young, apparently without knowing of the experiments of Mazeas, though they are fully detailed by Priestley, has described the very same colours under the name of the *colours of mixed plates*, and the merit of discovery of these colours has been ascribed to him by almost all modern writers. The method of producing the colours by suet, as given above by Mazeas, is exceedingly simple, while many persons have failed in repeating the experiments described by Dr. Young. It is to Dr. Young, however, that we owe the higher obligation of having discovered the general principle to which these colours must be referred, though he has not examined the phenomena with that attention which they merited. The following is the account which Dr. Young has given of the colours of mixed plates.

"I first noticed the colours of mixed plates, in looking at a candle through two pieces of plate glass, with a little moisture between them. I observed an appearance of fringes resembling the common colours of thin plates; and, upon looking for the fringes by reflection, I found that these new fringes were always in the same direction as the other fringes, but many times larger. By examining the glasses with a magnifier, I perceived that wherever these fringes were visible, the moisture was intermixed with portions of air, producing an appearance similar to dew. I then supposed that the origin of the colours was the same as that of the colours of halos; but, on a more minute examination, I found that the magnitude of the portions of air and water was by no means uniform, and that the explanation was therefore inadmissible. It was, however, easy to find two portions of light sufficient for the production of these fringes; for the light transmitted through the water, moving in it with a velocity different from that of the light passing through the interstices filled only with air, the two portions would interfere with each other, and produce effects of colour according to the general law. The ratio of the velocities, in water and in air, is that of 3 to 4; the fringes ought therefore to appear where the thickness is 6 times as great as that which corresponds to the same colour in the common case of thin plates; and, upon making the experiment with a plain glass and a lens slightly convex, I found the sixth dark circle actually of the same diameter as the first in the new fringes. The colours are also very easily produced, when butter or tallow is substituted for water; and the rings then become smaller, on account of the greater refractive density of the oils; but, when water is added, so as to fill up the interstices of the oil, the rings are very much enlarged; for here the difference only of the velocities in water and in oil is to be considered, and this is much smaller than the difference between air and water. It appears to be necessary for the production of these colours, that the glasses he held nearly in a right line between the eye and the common termination of a dark and luminous object; the portion of the rings, seen on the dark ground, is then more distinct than the remaining portion; and, instead of being continuations of the rings, they exhibit every where opposite colours, so as to resemble the colours of common thin plates seen by reflection, and not by transmission. In order to understand this circumstance, we must consider that where a dark object as A is placed behind the glasses, the whole of the light which comes to the eye, is either refracted through the edges of the drops, (as the rays B, C,) or reflected from the internal surface (as D, E,) while the light which passes through those parts of the glasses which are on the side opposite to the dark object, consists of rays refracted as before through the edges, (as F, G,) or simply passing through the fluid, (as H, I.) The respective combinations of these portions of light exhibit a series of colours of different orders, since the internal reflection modifies the interference of the rays on the dark side of the object, in the same manner as in the common colours of thin plates seen by reflection. When no dark object is near, both these series of colours are produced at once; and since they are always of an opposite nature at any given thickness of a plate, they neutralize each other, and constitute white light.

Fig. 115.



In applying the general law of interference to these colours, as well as to those of thin plates already known, it is impossible to avoid a supposition which is a part of the undulatory theory, that is, that the velocity of light is the greater, the rarer the medium; and there is also a condition annexed to this explanation of the colours of mixed plates, as well as to that of the colours of simple thin plates, which involves another part of the same theory; that is,

[1] See Dr. Young's Introduction to Medical Literature, p. 552.

Periodical Colours.

that where one of the portions of light has been reflected at the surface of a rarer medium, it must be supposed to be retarded one half of the appropriate interval; for instance, in the central black spot of a soap bubble, where the actual lengths of the paths very nearly coincide, but the effect is the same as if one of the portions had been so retarded as to destroy the other. From considering the nature of this circumstance, I ventured to predict, that if the two reflections were of the same kind, made at the surfaces of a thin plate of a density intermediate between the densities of the mediums containing it, the effect would be reversed, and the central spot, instead of black would become white; and I have now the pleasure of stating, that I have fully verified this conclusion by interposing a drop of oil of sassafras between a prism of flint-glass and a lens of crown-glass; the central spot seen by reflected light was white, and surrounded by a dark ring. It was however necessary to use some force, in order to produce a contact sufficiently intimate; and the white spot differed, even at last, in the same degree from perfect whiteness, as the black spot usually does from perfect blackness. There are also some irregularities attending the phenomena exhibited in this manner by different refracting substances, especially when the reflexion is total, which deserves farther investigation."

Recent experiments.

We are not aware that these interesting experiments of Mazeas and Dr. Young, have been repeated by any modern writer, our treatises on optics containing merely an abstract of Dr. Young's results. The subject has, however, been recently taken up by Sir David Brewster, who had found that the *colours of mixed plates*, in place of being merely the result of an experiment, was a *natural phenomenon* of a very interesting kind, which frequently presented itself in the examination of minerals. He was therefore led to attach a greater interest to the phenomena which they present. As the paper[1] which contains the results of his inquiries has not been published, we can only give a brief notice of them.

In order to produce these colours so as to be permanent, he found that the froth of albumen, (the white of an egg beat up into froth) ground circularly as it were between two thick plates of glass pressed firmly together, when the circular motion is stopped, exhibits the colours very splendidly. The glasses may then be held together by wax or by screws. If we desire to have a circular system of rings, we must use a convex lens in place of one of the plates. Whipped cream answers also very well; but paste that has become very smooth by age he found preferable to any other substance which he employed. When the experiment is successfully made, the colours are extremely splendid, the flame of a candle or other luminous body being of a bright colour complementary to that of the coloured light which surrounds it.

Upon looking with a microscope at the albumen or paste thus pressed into a film, it is found to resemble accurately the strata of cavities containing the new fluids, and sometimes water, as in *sulphate of lime*, &c., the paste being sometimes found in separate ramified patches of all shapes surrounded with air, while on some occasions numerous air cavities are included in the paste.

Although Dr. Young was correct in ascribing the colours of mixed plates to the interference of rays moving with different velocities in passing through the two contiguous media, yet his analysis of the phenomena is imperfect, and his determination of the interfering pencils incorrect. In his 39th lecture he ascribes "the colours seen in the dark part beyond the object, to the light scattered irregularly from the surfaces of the fluid,"[2] and in his description of fig. 115, above quoted, he specifies as the interfering portions which produce the colours, viz. *rays reflected* from the internal surface of the cavities, with *rays refracted* through the edges of the drops; and *rays refracted* through the edge with rays *simply passing* through the fluid. That the colours of mixed plates are not produced either by refracted or reflected pencils, is at once proved by the fact, that the same colours may be produced when the most refracting medium is terminated by a fine edge, and is itself a plate with perfectly parallel surfaces, so that there is no edge to reflect light, and no inclined faces to refract it. Having obtained this result, Sir David Brewster viewed the subject in another aspect, and has shewn that the phenomenon is entirely one of inflexion caused by the edge of a transparent inflecting body sufficiently thin to produce colours by the interference of the retarded light passing through the body close to its edge, with the light passing within the body close to its edge. The same pencils which interfere in the common case of a diffracting body interfere in the present case; but the pencils that pass through the transparent plate are modified by the retardation which they experience, so as to produce the phenomena of colours. The oppositely coloured pencils in mixed plates form part of the system of diffracted fringes, the colour seen upon the luminous body occupying the shadow of the diffracting edge, and the opposite colour seen around or beside the candle occupying the first fringe on each side of the shadow. The colours in the fringe on the left hand of the shadow of the diffracting edge, are seen by the eye on the right hand side of the candle, and those in the fringe on the right hand of the shadow are seen by the eye on the left hand side of the candle.

All the preceding phenomena may be produced by breaking down a thin transparent plate into minute portions, and when these portions are made to float in a fluid, or are placed between two plates of glass containing a fluid of nearly the same refractive power as the solid portions. The solid portions will thus act like much thinner plates placed in air, and we shall observe the identical phenomena which take place with the cavities in paste or albumen. When we examine with the microscope a very narrow portion of the solid substance bounded by lines nearly parallel, we perceive the phenomena of mixed plates under a new aspect. The space between the shadow of the two edges is filled up with a bright band of the colour which occupies the two first external fringes, and as the innermost fringe of each edge overlap each other, the colour has double the intensity. The same phenomenon is often seen in the parallel ramifications, or in the long cavities produced by the paste or albumen when the last act of friction was to move one of the plates of glass in a straight line.

The phenomena of mixed plates have been discovered by Sir David Brewster in *sulphate of lime*, in which there are shallow crystallised cavities in great numbers forming regular strata in the mineral. These cavities are filled with water, and in this case the diffracting edge is the edge of the cavity, and the light which passes through the water has its velocity greater than that which passes through the solid mineral.

In one remarkable circular stratum of cavities, all the cavities in the centre were the deepest, and gradually diminished in depth towards the circumference, till the microscope could scarcely resolve them. The highest orders of colours were therefore in the middle of the stratum, and they gradually descended to a white of the first order, at the circumference of the circular stratum.

An interesting experiment lately published by Henry Fox Talbot, Esq.[3] is a phenomenon of mixed plates, in which the densest of the plates is too thick to produce the colours at its edge in common light. "Make," says he, "a circular hole in a piece of card, of the size of the pupil

[1] This paper will probably appear in the *Phil. Trans.* for 1838, part i.

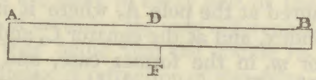
Double Refraction.

of the eye. Cover one half of this opening with an extremely thin film of glass (probably mica would answer the purpose as well or better.) Then view through this aperture a perfect spectrum formed by a prism of moderate dispersive power, and the spectrum will appear covered throughout its length with parallel obscure bands resembling the absorptions produced by iodine vapour. The cause of this phenomenon probably is, that one half of the light which passes through the glass film has its undulations thereby retarded by a certain quantity."

This phenomenon, which we have observed under various modifications, arises from the diffraction of the light passing on each side of and very close to the edge of the film; for if we cover this edge even with a fine wire, we obstruct the diffracted fringes modified by the retardation of the denser plate, and the phenomenon vanishes. Hence in order to see the fringes in perfection, we must make the aperture no wider than to include the space on each side of the edge of the film within which the light passes that is concerned in the phenomenon. As the light here used is perfectly homogeneous, the bands are alternately coloured and obscure.

Sir David Brewster has observed the fringes described by Mr. Talbot with thick plates having fine edges, and immersed in fluids, and even with plates of glass the 15th part of an inch thick, by looking through their edge upon a highly dispersed spectrum formed by a large refracting angle of a prism, and magnified by a powerful telescope. The perfection of the edge of the film, and an equality of thickness, are essential to the production of the fringes in their most interesting form. Sir David Brewster obtained them by looking through plates of sulphate of lime, where there were not properly speaking plates of different refractive powers, but where the plate suddenly became thicker, as shewn in the annexed figure, where AB, EC is the plate of sulphate of lime, which becomes thicker at E. When the eye looks through it at the spectrum in the direction ED, it sees the fringes which have the same magnitude as if the plate ADB were removed, and the eye looked only through the plate CE, in which case it is clearly a phenomenon of mixed plates.

Fig. 116.



When these dark lines were produced in great perfection, they had a sort of granular structure resembling fine screws at their edges, and sometimes appearing to enclose minute specks of light. Several other remarkable phenomena accompanying these fringes were communicated by the author to the British Association at Liverpool, and will appear in the next volume of the Philosophical Transactions.

PART. VI.—ON THE DOUBLE REFRACTION OF LIGHT.

Double refraction.

In the preceding part of this article we have supposed that when light is transmitted vertically through the surfaces or through the mass of transparent bodies, or when it passes obliquely and is refracted by the same bodies, it leaves the surface or emerges from the body in a single pencil, either perfectly white, or decomposed into a diverging beam of coloured light. This supposition is perfectly correct, under certain circumstances, for gaseous and fluid bodies, for glass slowly and equally cooled, and for a numerous class of crystallized bodies, whose primitive form is either the *cube*, the *regular octohedron*, or the *rhomboidal dedecahedron*. When these bodies have the same temperature and density throughout their mass, and are not exposed to any pressure, a pencil of light will be transmitted through them *single*, according to the laws already explained.

When a pencil of light falls upon all other bodies, such as artificial crystals, or salts on crystallized minerals, which have not the above primitive forms; upon animal substances, such as bone, horn, shell, hair, crystalline lenses of animal and elastic integuments; upon vegetable bodies, such as particular leaves, stalks and seeds; upon artificial bodies such as gums, resins, jellies, and solid bodies that have a variable density, during the transient passage of heat, or from rapid cooling, or unequal temperature and pressure:—when a pencil of light falls upon such bodies, it will be refracted into two distinct pencils, more or less inclined to each other according to the mechanical condition of the body, or to the direction in which the pencil passes through it. In some minerals and artificial crystals, this refraction of the two pencils is very great, and, generally speaking, is in such crystals, easily observed and measured; but in some cases it is not visible unless by transmitting the light through prisms of the body with large refracting angles; and in very many cases, the existence of two pencils is inferred only from certain other properties, which always accompany the property of giving double pencils. This separation of a single pencil into two, is called *double refraction*, and the bodies which have such a property are called *doubly refracting crystals* or *bodies*.

In many regular crystals there is *one line* through which, if a single pencil of light is transmitted, it does not experience double refraction. This line is called the *axis of the crystal*, or the *axis of double refraction*, and such crystals are denominated crystals with one axis of double refraction. In other crystals there are two lines through which, if the single pencil of light is transmitted, it does not experience double refraction. Such crystals are denominated crystals with two axes of double refraction. We shall treat of these two classes in separate sections.

SECT. I.—*On the Law of Double Refraction in Crystals with one Axis.*

As Bartholinus discovered the property of double refraction in the mineral called *Iceland spar*, *calcarcous spar*, or by chemists, *carbonate of lime*; and it is well fitted for exhibiting the phenomena, owing to its perfect transparency, and the great separation of the two pencils. This mineral consists, according to Stromeyer, of 56·15 parts of lime, and 43·7 of carbonic acid. It crystallises in the form of an obtuse rhombohedron, as shewn in fig. 117, where ABCB, ABCB, &c. are the faces of the rhombohedron, and AA′, the axis of the rhombohedron, on the two joining its two obtuse angles. The following are the dimensions of the crystal, as given by Malus, who observes that the first angle, from which all the rest are derived, is within *ten seconds* of the truth.

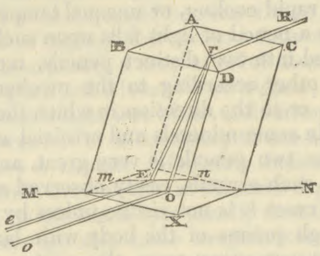
Double Refraction.

As Iceland spar cleaves equally in planes parallel to all its six faces, it is easy to cut out of any mass of it an accurate rhombohedron in which all the three sides AB, A′ B , A″B″, are equal; but for the purposes of experiment it is sufficient to have a piece with two smooth and parallel faces formed by cleavage, or ground and polished parallel to the cleavage planes.

Let AX be such a piece of Iceland spar, and ABDC its upper surface. If we place its lower surface upon a piece of paper having a black line MN, drawn upon it, and if we place the eye above the upper surface, we shall see the line MN distinctly doubled; or if it should appear single, the two images will separate, by turning the spar a little round, and the line will appear double as at MN, and *mn*. The one line will be found to coincide with the other, when MN is parallel to AD, the short diagonal of the rhomboidal face ABDC, and the lines will appear most separated, when MN is parallel, as in the figure, to the long diagonal BC. If a black spot is used in place of a line placed at O, it will appear double in every position, and in turning the crystal round, the other image E will seem to revolve round O.

Fig. 118.

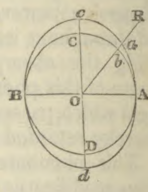


The best way, however, of shewing the double refraction of the Iceland spar, is to make a ray of light R*r*, fall upon the crystal at *r*. This ray will be refracted into two pencils or rays, *r*O, *r*E, and these will be again refracted at the second surface of the spar in directions E*e*, O*o*, parallel to the original ray R*r*. If we measure the angles of refraction of the fixed ray O*o*, corresponding to several angles of incidence from 0° to 90°, we shall find that these angles are always to one another in the constant ratio of 1 to 1·654, and that the refracted ray *r*O is always in the plane of incidence. It follows, therefore, that this ray is refracted as in water and glass, according to the ordinary law of refraction discovered by Snellius. Hence it is called the *ordinary ray*. But if we make the same experiments on the other ray *r*E, we shall find that at an incidence of 0°, in place of passing on unrefracted, it is actually refracted 6° 12′; that at other incidences its angles of refraction are not regulated by the law of Snellius, and that the ray *r*E is not in the plane of incidence. We conclude, therefore, that the ray *r*E is refracted according to some new or extraordinary law which remains to be investigated, and hence the ray *r*E is called the *extraordinary ray*.

If we grind down the two solid obtuse angles A, A′, fig. 116, so that the ground surfaces are perpendicular to the axis AA′, and if we polish their surfaces, and transmit a ray perpendicularly through them, so as to be parallel to the axis AA, we shall find that there is only one refracted ray, and hence there is no double refraction along the axis. Now this line AA′ is not a *fixed axis* like that of the earth ; it is merely a *fixed direction ;* for every line parallel to AA′ enjoys the property of an axis, as there is no double refraction in lines parallel to AA′.

In order to obtain an accurate idea of the law of extraordinary refraction, or that by which the extraordinary ray *r*E is regulated, let us take a rhomb, such as that shewn in fig. 117, and grind it into an accurate sphere, and then polish it. Let ACBD be such a sphere, AB being its axis of double refraction, corresponding with AA′ in fig. 117, and let O be its centre. If we now bend a piece of sheet lead or sheet copper into an arch ADB, and making a small hole in it opposite to A, and another opposite to B, cement a handle to it about D, it will enable us, in the following manner, to detect the general law of extraordinary refraction. The use of the two holes in this experiment is to ensure that the light admitted through one of them, and emerging at the other, shall pass through the centre O of the sphere. Let one of the holes be now placed in the surface of the sphere at A, and the eye at the other hole at B, the hole will appear single, shewing that the double refraction is there nothing. Let the hole be shifted gradually from A to C, and the other hole will move from B to D. In the different positions from A to C, it will be seen that the hole begins to become double on leaving A, and that the distance of the two images of it gradually increases from A to C, where it becomes a maximum. The same result will be obtained by making the hole move from A to D, or in any quadrant of the sphere passing through the poles A and B. The very same result will be obtained if the hole moves from B to C, or from B to D. If we now make one of the holes move along the equator COD, we shall find that by placing the eye at the other hole, the distance of the images will be exactly the same, or the double refraction the same in every part of the equator. Hence the general law of double refraction in crystals with one axis, is a very simple one : it is nothing at the poles; it increases gradually from the poles to the equator, where it is a maximum ; it is the same in the same parallels of latitude; and the preceding experiments will also shew that the line joining the centres of the two images is in the plane of the meridian.

Fig. 119.



Let the index of extraordinary refraction be now measured at the pole A, where it is the same as the ordinary index, and at the equator C, and it will be found to be 1·654, or m, in the former case, and 1·488, or m', in the latter. Now Huygens was led by a theory which has been explained under CHROMATICS, to the following law, which he verified by experiment, and which has been confirmed by the experiments of Wollaston, Malus, and other philosophers. Upon the axis AB of the sphere, fig. 118, describe an ellipse A*c*, B*d*, whose lesser axis AB is to its greater axis *cd* as $\frac{1}{m}$ is to $\frac{1}{m'}$, or as $\frac{1}{1·654}$ is to $\frac{1}{1·488}$, or as ·604 to ·674 ; and if an oblate spheroid is supposed to be generated by the revolution of this ellipse round its lesser axis AB, the reciprocal of the index of refraction of the extraordinary ray at any point of the spheroid will be measured by its radius at that point; that is, if R*ab*O is a ray incident at *b*, the radius $\frac{1}{Oa}$ will be the extraordinary index of refraction for that ray. If we therefore make

φ=ROA, or the inclination of the incident ray to the axis.
R=*cd*, the major axis of the spheroid.
r=AB, the lesser axis.

Then it may be shewn, as Malus has done,[1] that

$$Oa = \frac{Rr}{\sqrt{(r^2 \sin.^2\varphi + R^2 \cos.^2\varphi)}};$$

[1] *Theorie de la Double Refraction*, p. 143.

and as the index of refraction of the extraordinary ray is the reciprocal of this radius, we have

$$m' = \frac{\sqrt{(r^2 \sin.^2 \varphi + R^2 \cos.^2 \varphi)}}{Rr}, \text{ or}$$

$$m'^2 = \frac{1}{r^2} - \left(\frac{R^2 - r^2}{R^2 r^2}\right) \sin.^2 \varphi.$$

In the case of Iceland spar, we have

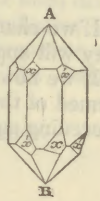
$$m'^2 = 2{\cdot}736693 - 0{\cdot}536510 \sin.^2 \varphi, \text{ or}$$

$$m' = \sqrt{2{\cdot}736693 - 0{\cdot}536510 \sin^2 \varphi}.$$

As the index of extraordinary refraction thus found, is always equal to the index of the ordinary refraction *minus*, another quality which depends on the difference between the radius of the sphere and that of the spheroid, the crystals in which this happens may be called *negative* doubly refracting crystals.

The preceding law of double refraction was believed by Malus to be universal, and applicable to all crystals that had this property. M. Biot, however, discovered that in quartz or rock crystal the extraordinary ray had its index of refraction m' greater than the ordinary index m. This mineral crystallises in six-sided prisms, as shewn in the annexed figure, terminated by six-sided pyramids, A and B. If we grind down and polish the summits A and B of a large crystal, perpendicular to the axis AB, and if we determine the index of refraction when the rays pass along AB, we shall find it to be as Malus found it, 1·5484, and without any double refraction, and 1·5544 in a direction perpendicular to the axis.

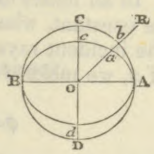
Fig. 120.



If we now grind the crystal into a sphere ACBD, fig. 121, and if we perform the very same experiments with it as we did with Iceland spar, we shall obtain analogous results. The double refraction will be found to increase from the poles A, B, to the equator CD, and to be the same in every part of the equator, and in each parallel of latitude; the only differences between it and calcareous spar being that the double refraction is less, and that the index of refraction of the extraordinary ray is always *greater* than that of the ordinary ray.

The extraordinary refraction of quartz will, therefore, as M. Biot has shewn, be represented by a prolate spheroid generated by the revolution of the ellipse A*c*B*d*, whose greater axis AB is to the lesser *cd* as $\frac{1}{1{\cdot}5484}$ is to $\frac{1}{1{\cdot}5544}$, or as ·6458 is to ·6418. Hence, if R*ba*O is a ray incident on the sphere at *b*, the radius $\frac{1}{Oa}$ will be the index of extraordinary refraction for that ray. Hence we shall obtain

Fig. 121.



$$Oa = \frac{Rr}{\sqrt{(r^2 \sin.^2 \varphi - R^2 \cos.^2 \varphi)}}, \text{ and}$$

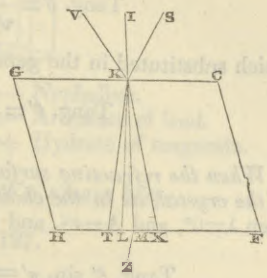
$$m^2 = \frac{1}{r^2} + \frac{R^2 - r^2}{R^2 r^2}, \sin.^2 \varphi.$$

Hence, as the index of extraordinary refraction is equal to the index of ordinary refraction, *plus*, another quantity depending on the difference between the radius of the sphere and that of the prolate spheroid, crystals which have this property may be called *positive* doubly refracting crystals.

The following geometrical rule of finding the direction of the extraordinary ray, when the incident ray forms different angles with the axis given by Huygens,[1] may be interesting to some of our readers. Let CGHF be what is called the *principal section* of a crystal of calcareous spar, &c., or a plane passing through the axis, which will be in the direction CH. Let SK, VK, be rays incident on that plane upon the surface CG, and equally inclined to IKL, perpendicular to the surface at the point of incidence K; then if KM is the refracted ray, corresponding to a ray IK, incident perpendicularly, the other rays VK, SK, will be refracted in directions KT, KX, so that TM is equal to XM.

Double Refraction.

Fig. 122.



Although the determination of the extraordinarily refracted ray is very simple, when the crystal is supposed to be spherical, yet the formula becomes complicated when we suppose the ray incident in any given direction upon a natural surface of Iceland spar. Malus has investigated such a formula, but our limits will not allow us to give more than the resulting expression.

Making θ = the angle of incidence,

θ' = the angle of extraordinary refraction,

π = the azimuth of incidence, or the angle which the plane of incidence forms with the axis.

π' = the same angle for the extraordinary ray.

λ = the inclination of a line perpendicular to the face of incidence to the axis of the crystal.

$A = R^2 \sin.^2 \lambda + r^2 \cos.^2$,

$C = \sin. \lambda \cos. \lambda\, (R^2 - r^2)$. Then

$$\text{Tang. } \theta' \cos. \pi' = \frac{R^2 r^2 \sin. \theta \cos. \pi}{A\sqrt{A - R^2 \sin.^2 \theta\, (r^2 \cos.^2 \pi + A \sin.^2 \pi}} + \frac{C}{A},$$

and

$$\text{tang. } \theta' \sin. \pi' = \frac{R^2 \sin. \theta \sin. \pi}{\sqrt{A - R^2 \sin.^2 \theta\, (r^2 \cos.^2 \pi + A \sin.^2 \pi.)}}$$

When the refracting surface is parallel to the axis, (as in the six-sided prism of calcareous spar), we shall have $\lambda = 90$, in which case $A = r^2$ and $C = 0$. The formula then becomes

$$\text{Tang. } \theta' \cos. \pi = \frac{r^2 \sin. \theta \cos. \pi}{R\sqrt{1 - \sin.^2 \theta\, (r^2 \cos. \pi + R^2 \sin.^2 \pi)}}.$$

$$\text{Tang. } \theta' \sin. \pi = \frac{R \sin. \theta \sin. \pi}{\sqrt{1 - \sin.^2 \theta\, (r^2 \cos.^2 \pi + R^2 \sin.^2 \pi)}}.$$

and dividing the one equation by the other, we have

$$\text{Tang. } \pi' = \frac{R^2}{r^2} \text{tang. } \pi.$$

When the refracting surface is parallel to the axis, and the plane of incidence perpendicular to the axis, then $\pi = \pi' = 90°$, or $\lambda = 90$; consequently $\cos. \pi' = 0$, and the first equation becomes

$$\text{. Tang. } \theta' = \frac{R \sin. \theta}{\sqrt{1 - R^2 \sin.^2 \theta'}} \text{ and } \sin. \theta' = R \sin. \theta.$$

When the refracting surface is parallel to the axis, and the plane of incidence passes through the axis, in which case the refraction is in the plane of a *principal section*, then $\pi = \pi' = 0°$, the second equation becomes

[1] *Traité de la Lumière*, sect. 17.

Double Refraction.

$$\text{Tang. } \theta' = \frac{r}{\text{R}} + \frac{r \text{ sin. } \theta}{\sqrt{1 - r^2 \text{ sin.}^2 \theta}},$$

or, by substituting r sin. θ for its equal sin. θ, we have

$$\text{Tang. } \theta' = \frac{r \text{ sin. } \theta}{\sqrt{1 - r^2 \text{ sin.}^2 \theta}},$$

which substituted in the general formula, gives

$$\text{Tang. } \theta' = \frac{2}{\text{R}} \text{Tang. } \theta.$$

When the refracting surface is perpendicular to the axis of the crystal, as in the chaux carbonatée baseé of Hauy, then $\lambda = 0°$, and $\text{A} = r^2$, and $\text{C} = 0$. Hence

$$\text{Tang. } \theta' \text{ sin. } \pi' = \frac{\text{R}^2 \text{ sin. } \theta \text{ sin. } \pi}{r \sqrt{1 - \text{R}^2 \text{ sin.}^2 \theta'}},$$

$$\text{Tang. } \theta \text{ Cos. } \pi' = \frac{\text{R}^2 \text{ sin. } \theta \text{ cos. } \pi}{r \sqrt{1 - \text{R}_2 \text{ sin.}^2 \theta}}.$$

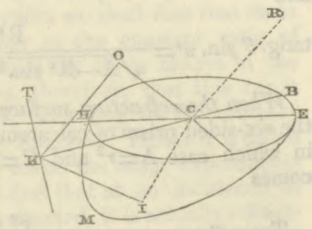
and dividing the one equation by the other we have

Tang. π' = Tang. π, and $\pi' = \pi$, which shews that the refracted ray is in the plane of the incident ray. Hence we obtain from the preceding equation,

$$\text{Tang. } \theta' = \frac{\text{R}^2 \text{ sin. } \theta}{r \sqrt{1 - r^2 \text{ sin.}^2 \theta}}$$

In order to find the path of the extraordinarily refracted ray, Huygens has given the following elegant geometrical construction. Let EBH be the elliptical section of the oblate spheroid which regulates the double refraction of the crystal, formed by the surface upon which the ray is incident. Let the ray RC fall upon its centre, and let BCK be the intersection of the plane of incidence with the face of the crystal. Let EMH be a part of the oblate spheroid within the crystal or below its surface, the axis of the spheroid passing through and having any inclination to the surface. Then draw in the plane KCR a line CO perpendicular to RC, and having drawn OK perpendicular to OC, or parallel to CR, make OK equal to $\frac{1}{3m \text{ incid.}}$ or the reciprocal of the sine of the angle of incidence. Through K draw KT perpendicular to the plane of incidence BRCK, and through KT draw a plane which shall touch the spheroid. Let I be the point where this plane touches the spheroid, then drawing the line CI, this line will be the extraordinarily refracted ray.

Fig. 123.



Doubly refracting lenses.

As there are several researches and instruments in which it may be required to find the focus of the extraordinary pencil when the doubly refracting substance has the form of a lens, we shall here give the formula obtained by Malus. Calling r, r' = the radii of the anterior and posterior surfaces of a convex lens,

d = the distance of the radiant point,

a = the larger semi-axis of the spheroid of double refraction.

b = the shorter semi-axis of do.

F = the focal length for the ordinary ray.

f = the focal length of the extraordinary ray, when d is infinite, or the rays parallel, and

φ = the focal length of the extraordinary ray required.

Thus Malus has shewn that

$$\varphi = -\frac{a^2 bdrr'}{d(r+r')(2b^2 - a^2 - a^2 b) - a^2 brr'};$$

$$\text{F} = \frac{-brr'}{(r+r')(1-b)}.$$

When the radii r, r', are equal, or the lens *equally convex*, we have

$$\varphi = -\frac{a^2 bdr}{2d(2b^2 - a^2 - a^2 b) - a^2 br},$$

$$f = -\frac{a^2 br}{2(2b^2 - a^2 - a^2 b)}.$$

If we suppose a to be equal to b, or the spheroid to become a sphere, by which the ordinary refraction is regulated, we obtain for the ordinary ray,

$$\text{F} = \frac{br}{2(1-b)}.$$

Hence, the difference between the ordinary and extraordinary focal lengths will be

$$f - \text{F} = 2\text{ F} \frac{a^2 - b^2}{2b^2 - a^2 - a^2 b}.$$

If we change the signs of r and r' in these expressions, they will apply to *concave* lenses.

Lens of Iceland spar.

If we now take *Iceland spar*, and suppose the lens to be formed of that substance, we have only to substitute in the preceding equation, the following values of a and b,[1] viz.:—

$a = 0{\cdot}6741717$
$b = 0{\cdot}6044871$, whence
$m = 1{\cdot}65429$
$m' = 1{\cdot}48330$,

we obtain

$\varphi = -r.\ 8{\cdot}8228602$
$\text{F} = -r.\ 0{\cdot}764180$
$f - \text{F} = -\text{F}.\ 114{\cdot}4546$

In the case of *quartz* or *rock crystal*, where

$a = 0{\cdot}645813$
$b = 0{\cdot}641776$
$m = 1{\cdot}558176$
$m' = 1{\cdot}548435$,

we obtain

$\varphi = -r.\ 0{\cdot}962824$
$\text{F} = -r.\ 0{\cdot}895775$
$f - \text{F} = -\text{F}.\ 0{\cdot}074846.$

In all lenses of the same substance, the ratio of f to F will be constant, whatever be the form of the lenses, provided the incident rays are parallel. If, in the general expression of φ, we make d infinite, we have

$$\varphi = \frac{a^2 brr'}{(r+r')(2b^2 - a^2 - a^2 b)}.$$

and making $a = 0$, we have for the ordinary ray,

$$\text{F} = -\frac{brr'}{(r+r')(1-b)},$$

whence

$$\frac{\varphi}{\text{F}} = \frac{a^2(1-b)}{2b^2 - a^2 - a^2 b}.$$

a result independent of the values of r and r'.[2]

The focus of the rays refracted extraordinarily by a doubly refracting lens, becomes more and more distant, as

[1] Malus, *Theorie*, &c., p. 278, sect. 66.

[2] Id. Id. p. 281, sect. 66.

Double Refraction.

the axis of double refraction of the crystal approaches to the axis of the lens; and the preceding formulæ apply solely to the case where these two axes are parallel, as it is only in that case that such lenses can be of any use.

List of the Primitive Forms and Crystals which have one axis of Double Refraction.

From a very extensive series of experiments on the double refraction of crystallised bodies, Sir David Brewster was led to the general law, that all crystals whose primitive form has only *one axis* of figure, or one pre-eminent line, round which the matter of the crystals is symmetrically arranged, had also *one axis* of double refraction, and that their axis of figure was likewise the axis of double refraction.

The following are the primitive forms which possess this geometrical and optical property:—

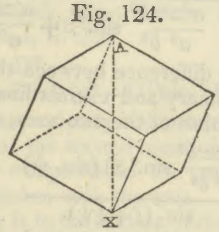
The rhombohedron with an obtuse summit.
The rhombohedron with an acute summit.
The regular six-sided prism.
The octohedron with a square base.
The right prism with a square base.

Table of Crystallised Minerals and other bodies which have one axis of double refraction.

In the following table the crystals are arranged under their primitive forms, so far as these forms have been determined by crystallographers. The sign + indicates that the crystals have *positive* double refraction, like *quartz*, and — that they have *negative* double refraction, like *Iceland spar.*

1. *Rhombohedron with an obtuse summit.*

Fig. 124.



— Carbonate of lime (Iceland spar).
— Carbonate of lime and iron.
— Carbonate of lime and magnesia.
— Phosphato-arseniate of lead.
— Carbonate of zinc.
— Nitrate of soda.
— Phosphate of lead.
— Ruby silver.
— Levyne.
— Tourmaline.
— Rubellite.
— Alum stone.
— Gmelinite.
— Chlorate of soda.
+ Dioptase.
+ Quartz.

2. *Rhombohedron with acute summit.*

— Phosphate of ammonia and magnesia.
— Sulphate of nickel and copper.
— Hydrate of strontites.
+ Apophyllite of Uton.
+ Oxahverite.
+ Superacetate of copper and lime.
+ Titanite.
+ Ice, certain crystals.
Murio-carbonate of lead.

The following crystals and organised bodies have one axis of double refraction, but their primitive form has not been accurately determined.

	Position of the axis.
— Muriate of lime..	Axis of six-sided prism.
— Muriate of strontian........	Do. do.
— Hyposulphate of lime[1]	Axis of hexagonal tables.
— Mica from	Perpendicular to laminæ.
— Mica, with amianthus.......	Perpendicular to the laminæ.
— Nacre, (See *Phil. Trans.* 1836, p.)...........	Perpendicular to laminæ.
+ Boracite..........................	Axis of rhomb of 90°.
+ Apophyllite, (*surcomposee* of Hauy),...	Perpendicular to the table.
+ Sulphate of potash and iron,......................	Axis of six-sided prism.
Tortoise shell, (Sir. J. Herschel),..............	

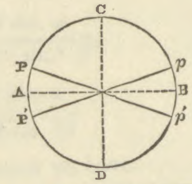
[1] Sir John Herschel.

Sect. II.—*On the Law of Double Refraction in Crystals with two axes.*

When M. Malus published his theory of double refraction, and even so late as 1816, all crystals were believed to have only one *axis* of double refraction, one of the rays being refracted by the ordinary law, and the other by the extraordinary law, above explained. During the examination of an extensive class of minerals and artificial salts, Sir David Brewster was led to the discovery of crystals with *two axes of double refraction.*

The general character of the phenomena presented by such crystals will be understood from fig. 129, where we may suppose, as before, the crystal to have the form of a sphere. In place of there being one line along which there is no double refraction, there are two such as P*O*p, P′*O*p′, in which the incident pencil is not divided into two. The double refraction increases on each side of these axes, from P, to C and A, and from P′ to D and A. The double refraction increases in the very same manner from *p* to C and B, and from *p*′ to D and B, according to a law which will afterwards be explained.

Fig. 129.



In continuing his investigations, Sir David Brewster found crystals in which the axes P*O*p, P′*O*p′ formed all possible angles with each other from 0° up to 90°, and he was led also to the important result, that these two axes were not real axes of double refraction like those in uniaxal crystals, but were only *resultant axes*, as he called them, or *axes of compensation.* The grounds on which he formed this opinion were, that these lines P*O*p, P′*O*p′ had no relation whatever to any fixed or permanent lines in the primitive form of the crystals, like the axes of uniaxal crystals, and that the double refraction did not altogether vanish along these lines, as in Iceland spar and other minerals with no axis. He was led to these results, not by measuring the double refraction itself, but by the phenomena which will be presently explained. At this time it was the opinion of our author, and afterwards that of M. Biot and other distinguished philosophers, that in *biaxal* as in uniaxal crystals, one of the rays was refracted according to the ordinary law of Snellius, and the other according to an extraordinary law, and hence the investigation of the extraordinary law occupied the attention of our author.

In commencing this inquiry, he assumed as the two real axes of double refraction, the line AB bisecting the angle formed by the apparent or resultant axes P*O*p, P′*O*p′, and another line at right angles to it, viz. either the line CD, or the line perpendicular to it passing through O.

If the principal axis AB is *positive*, then if we assume O as the second axis, it must be taken *positive* also; but if CD is assumed as the second axis, it must be taken *negative.* Now, it is obvious that if we take AB as a *positive*, and CD as a *negative* axis, the double refraction in the direction AB is the maximum double refraction of the axis CD, because the effect of the axis AB is here nothing. In like manner, the double refraction along CD is a measure of the maximum double refraction of the axis AB. Hence we can easily ascertain the relative intensities of the doubly refracting force of each axis AB and CD. Having done this, the next step was to compute the double refraction at the point P produced by the positive axis AB acting alone as a single axis, and also the double refraction produced at the same point P, by the negative axis CD. When this was done, the two double refractions were found to be equal and opposite, and hence they compensated each other, and produced an axis P*p*, in which there was no double refraction, and which was the resultant of the actions of AB and CD.

In this way, and by experiments which will be related in a subsequent chapter, our author was led to the following method of finding the general law of extraordinary refraction in biaxal crystals.

Make b = axis of revolution of the two spheroids.
a, a' = the other axis of the spheroid.
β, β' = the inclination of the incident ray to the axes of the crystal.
ψ = the angle of the doubly refracting forces emanating from each axis.
ζ = half the difference of the angle at the base of the parallelogram of forces.

Then, as the velocity of the ray is inversely as the variable radius of the spheroid, $\frac{1}{b^2}$ will be the square of the velocity of the ordinary ray, and $\frac{1}{a^2}, \frac{1}{a'^2}$ the square of the minimum velocity of the extraordinary ray, in virtue of the separate action of each axis, AB and CD. Hence the difference between the squares of the velocities of the ordinary and extraordinary rays will be

$$\left(\frac{a^2 \pm b^2}{a^2 b^2}\right) \sin.^2 \beta$$

$$\left(\frac{a'^2 \pm b^2}{a'^2 b^2}\right) \sin.^2 \beta$$

the sign being positive when the axis is positive, and *vice versa.* But as these expressions represent the sides of the parallelogram of forces, we have

$$\text{Tang. } \zeta = \frac{\left(\frac{a^2 \pm b^2}{a^2 b^2} \sin.^2 \beta\right) - \left(\frac{a'^2 \pm b^2}{a'^2 b^2} \sin.^2 \beta'\right) \text{tang. } \tfrac{1}{2}\psi}{\frac{a^2 \pm b^2}{a^2\, b^2} \sin.^2 \beta + \frac{a' \pm b^2}{a'^2 b^2} \sin.^2 \beta'.}$$

Consequently the difference between the squares of the velocities of the ordinary and extraordinary ray produced by the combined action of the two axes, will be

$$\frac{\left(\frac{a^2 \pm b^2}{a^2\, b^2} \sin.^2 \beta\right) (\sin.\ \psi)}{\sin.\ (\zeta + \frac{1}{2}\psi).}$$

Hence, calling V the velocity required, we have

$$V^2 = \frac{1}{b^2} + \frac{\left(\frac{a^2 \pm b^2}{a^2\, b^2} \sin.^2 \beta\ (\sin.\ \psi)\right.}{\sin.\ (\zeta + \frac{1}{2}\psi)}, \text{ and}$$

$$V = \left|\frac{1}{b^2} + \frac{\frac{a^2 \pm b^2}{a^2\, b^2} \sin.^2 \beta)\ (\sin.\ \psi)}{\sin.\ (\zeta + \frac{1}{2}\psi)}\right|^{\frac{1}{2}}$$

The form of the compound, or irregular spheroid, may therefore be computed for all doubly refracting crystals.

The general law of extraordinary refraction which has now been explained, may be thus expressed.

The increment of the square of the velocity of the extraordinary ray produced by the action of two axes of double refraction, is equal to the diagonal of a parallelogram whose sides are the increments of the square of the velocity produced by each axis separately, and calculated by the law of Huygens, and whose angle is double of the angle formed by the two planes passing through the ray and the respective axes.

When the two axes are of equal intensity, and of the same character, the preceding law gives the very same results as the law of Huygens does for one axis placed at right angles to the other two.

From these views it follows as a necessary consequence, a consequence first deduced from them by M. Biot, that the difference of the squares of the velocities of the two rays are proportional to the product of the sines of the angles which each of them make with the two resultant axes P and P′, and hence making these angles φ and φ', and V the velocity of the extraordinary, and v that of the ordinary ray, we shall have $V = (v^2 + a \sin.\varphi \times \sin.\varphi')^{\frac{1}{2}}$, a being a constant coefficient.

Fres- law.

M. Fresnel was led by theoretical considerations to suppose that in crystals with two axes, the law of double refraction was still more complicated; and he soon confirmed the accuracy of his views by direct experiment, and was thus able to establish a general law which embraced all crystals with one axis.

Our limits will not allow us to do more than give the following brief abstract of his labours, which we owe to M. Pouillet.[1]

When the light is incident in the plane perpendicular to AB, fig. 129. that is in the plane of CD, *one* of the *two* rays is regulated by the ordinary law of refraction, whereas when the ray is incident in the plane AB, perpendicular to the axis CD, the *other* of the two rays is regulated by the ordinary law of refraction. The formulæ by which Fresnel expressed his law, are as follow:

making V=the velocity of the ordinary ray.

v=that of the extraordinary ray.

A=the angle of the ray with the one axis.

a=the angle of the ray with the other axis.

D=*ordinary* velocity in *uniaxal* crystals, or the *constant* velocity in the section perpendicular to CD, fig. 129, in *biaxal* crystals.

d'=the *extraordinary* velocity in *uniaxal* crystals, or the *constant* velocity in the section perpendicular to AB, fig. 129, then

$$V^2 = D^2 + (d^2 - D^2)\sin^2\tfrac{1}{2}(a - A)$$
$$v^2 = D^2 + (d^2 - D^2)\sin^2\tfrac{1}{2}(a + A)$$

In *uniaxal crystals*, when the *two* axes are reduced to *one*, we have A=a, so that

$$V^2 = D^2$$
$$v^2 = D^2 + (d^2 - D^2)\sin^2 A,$$

that is, the ordinary velocity is constant in all directions and equal to D, and, as the second equation indicates, the extraordinary velocity v depends on the angle A, which the extraordinary ray makes with the axis.

When this ray is in the section perpendicular to the axis, we have A=90°, and $\sin.^2 A = 1$, hence $V' = d$.

When the ray is parallel to the axis A=0°, and $\sin.^2 A = 0$, whence v=D, so that in this direction only the extraordinary becomes equal to the ordinary velocity.

In *biaxal crystals*, when the ray is in the section perpendicular to CD, fig. 129, it is evident that it always forms equal angles with the axes Pp, P′p'. Hence A=a, and $\sin.^2\frac{1}{2}(a - A) = 0$, consequently $V^2 = D^2$, or V=D. In this way D is the expression of the velocity in this case, and it is on this account that the term *ordinary velocity* is applied to all those which are given by the different values of V.

When the ray on the contrary, is in the section perpendicular to AB, the sum of the angles A and a is always equal to two right angles, and $\sin.\frac{1}{2}(A + a) = 1$, whence it follows that $V^2 = d^2$, and V=d, and it is on this account that the term *extraordinary velocity* is applied to all those that are given by the values of v.

When d is greater than D, the *minimum* of the ordinary velocity takes place when a=A, or when V=D, and the *maximum* takes place when a—A is the greatest possible, which happens in the plane of the axes APCBDP′. The *minimum* becomes the *maximum*, and *vice versa* when D is greater than d. The *maximum* and *minimum* for the extraordinary ray take place also, when $v=d$, and consequently for the case when the ray is in the plane of the axes, but they in like manner change their part when d is greater or less than D.

In every case the difference of the squares of the velocities is expressed by the formula

$$v^2 - V^2 = (d^2 - D^2)\sin.a.\sin.A.$$

That is to say, the two ordinary and extraordinary rays having a common direction, the difference of the squares of their velocities are proportional to the product of the sines of the angles which each of them makes with the two axes. "This remark, adds M. Pouillet, had been made by Sir David Brewster and M. Biot before Fresnel had pointed out the simple law which embraces the phenomena in all its extent."

List of the primitive forms of Crystals that have two axes of double refraction.

Crystals with two axes.

From a great number of experiments, Sir David Brewster found that the property of possessing *two* axes of double refraction belonged to all the crystals that are included in the *prismatic system* of Mohs, or which have the following primitive forms of Hauy:—

A right prism,	Base a rectangle.
———	Base a rhomb.
———	Base an oblique parallelogram.
Oblique prism	Base a rectangle.
———	Base a rhomb.
———	Base an oblique parallelogram.
Octohedron	Base a rectangle.
———	Base a rhomb.

In these solids there is no single line or axis of symmetry.

The following table, which we could have enlarged considerably, contains most of the crystals with two axes, whose primitive forms have been determined by crystallographers:—

1. *List of Crystals of known Primitive Forms, and having Two Axes of Double Refraction.*

1. *Right Quadrangular Prism—Base a Rectangle.*

	Position of Principal Axis.	*Position of Second Axis.*
Cymophane, *Young.*	Axis of right prism.	Perp. to the sides.
Peridot, ditto.	Perp. to axis.	Axis of right prism.
Prehnite, ditto.		
Stilbite, ditto.	Parallel to longest side of prism, or perp. to best cleavage planes.	Axis of right prism, or perp. to longest faces.
Comptonite, *Brooke.*	Perp. to axis of right prism.	Axis of that prism, or other axis.
Thomsonite, ditto.	Perp. to axis of prism.	Axis of the prism.
Anhydrite, *Bournon.*	Axis of right prism.	Perp. to sides of prism
Tartrate of potash, ditto.	Perp. to the flat rhomb. faces.	Parallel to a side of rhomb. prism.
Staurotide, *Hauy.*		
Datholite, do.		
Mica, do.	Axis of right prism.	Greater diagonal of its rhomb. base.
Talc, do.	Axis of right prism.	Diagonal of its rhomb base.
Spodumene, do.	Axis of prism.	In plane of laminæ.
Sulphate of barytes, ditto.	Short diagonal of rhomb. base.	Long diagonal, or axis of prism.
Sulphate of strontian, do.	Axis of the prism.	Perp. to axis of prism.
Sulphate of soda, *Bournon.*		
Citric acid, do.		
Tartrate of potash and soda, do.		
Chromate of lead, do.		
Stilbite, *Brooke.*	Perp. to laminæ.	In plane of laminæ.
Mesotype of Auvergne, do.	Axis of prism.	Perpendicular to axis.

Double Refraction

3. *Right Quadrangular Prism—Base an Oblique Parallelogram.*

Names of Minerals.	*Position of Principal Axis.*	*Position of Second Axis.*
Needlestone of Faroe, do.	Axis of prism.	Perpendicular to axis.
Sulphate of lime, *Hauy.*	In plane of the laminæ.	Axis of prism.
Epidote, do.	In base of prism.	Axis of prism.
Axinite, do.		
Heulandite, *Brooke.*		
Brewsterite, do.		
Sulphato-carb. of lead, do.	Perp. to laminæ.	In plane of laminæ.
Acetate of strontian.		

4. *Oblique Quadrangular Prism—Base a Rectangle.*

Borax, *Hauy.*
Euclase, do.

5. *Oblique Quadrangular Prism—Base a Rhomb.*

Diopside, *Hauy.*	Perpendicular to sides of the prism.	Axis of prism, or other axis.
Euclase, do.		
Augite, do.		
Glauberite.		
Grammatite.		
Sulphate of iron, *Wollaston.*		
Super-sulphate of potash, *Bournon.*	Perp. to axis of prism.	Axis of prism.
Acetate of copper, do.	Perp. to axis of prism.	Axis of prism.
Tartaric acid, do.	Axis of prism.	Perpendic. to faces.
Oxalic acid, do.		
Sugar, do.		
Hydrate of strontian.		
Bitartrate of potash.		
Sulphate of soda.		

6. *Oblique Quadrangular Prism—Base an oblique Parallelogram.*

Feldspar, *Hauy.*
Kyanite, do.
Sulphate of copper, do.

7. *Octohedron with a Rectangular Base.*

Nitrate of potash.	Axis of octohedron.	Perp. to sides of base
Arragonite.	Axis of prism or perpendicular to axis of octohedron.	Perp. to sides of base
Carbonate of lead.	In plane of base of two pyramids.	Axis of the octohedron.
Sulphate of lead.	Axis octohedron.	Perp. to sides of rect. base.
Topaz.		
Muriate of copper.	Long diagonal of rhomb. base.	Short diagonal of the rhomb. base.

8. *Octohedron with a Rhombic Base.*

Sulphur, *Hauy.*		
Sphene, do.		
Carbonate of soda, do.	Diagonal of base through *o* of Hauy, Pl. xxxix.	Axis of octohedron or other axis.

9. *Minerals belonging to the Prismatic System of Mohs, and having* TWO *axes, but not included in any of the above divisions of Hauy.*

Names of Minerals.	*Position of Principal Axis.*	*Position of Second Axis.*
Sulphate of magnesia, *Mohs.*	Cleavable diagonal of square base.	Perpendicular to axis, or the other diagonal.
Sulphate of manganese.		
Sulphate of zinc.	Axis of rhomboidal prism.	Short diagonal of rhomboidal base.
Sulphate of ammonia.	Axis of hexahed. prism.	Perp to axis.
Sulphate of cobalt.		
Carbonate of strontian, do.	Axis of prism.	Perp. to axis.
Carbonate of barytes, do.	Axis of prism.	Perp. to axis.
Diallage.	Perp. to plates.	Plane of plates.
Molybdate of ammonia.		
Muriate of barytes.		
Realgar.		
Orpiment.	In plane of laminæ.	Perp. to laminæ.
Lepidolite.	Perp. to laminæ.	Plane of laminæ.
Mesotype.	Axis of prism.	Perp. to axis.
Mesolite.	Ditto.	Ditto.
Serpentine.		
Natrolite.		
Sulphato-bi-carbonate of lead.	Axes of acute rhomb.	In plane of laminæ.
Phosphate of iron.	In plane of laminæ.	Perp. to laminæ.
Harmotome, Petalite, Chabasie.		

10. *Crystals, whose primitive form has not been determined, but which have been found to have two axes, and which must belong to the Prismatic System of Mohs.*

Iolite.	Axis of prism.	Perp. to axis of prism.
Indurated talc.	Perp. to plates.	In plane of laminæ.
Carbonate of potash.	Plane of axis perpendicular to the flat tables.	In plane of tables.
Carbonate of copper.		
Sulphate of ammonia and magnesia.	Shorter diagonal of the rhomboidal base.	Axis of hexagonal prism, or long diag. of rhomb. base.
Sulphate of soda and magnesia.		
Sulphate of nickel.	Short diagonal of the rhomboidal base.	Axis of prism, or other axis.
Oxy-nitrate of silver.	Perp. to rhomb plates	Long diagonal of rhomboidal plates.
Nitrate of ammonia.		
.... of lime.		
.... of strontian, with water of crystallization.		
.... of copper.		
.... of zinc.		
.... of mercury.		
.... of bismuth.		
Nitrate of lead, certain specimens.	Mr. Herschel, *Edin. Ph. Jour.* vol. ii. p. 184.	
Muriate of mercury.		
.... of magnesia.		
Acetate of lead.	Perp. to broad sides of prism.	Axis of prism, or other axis.
.... of zinc.	In plane of hexag. plates.	Perpendicular to hexag. plates.
.... soda.		
.... barytes.		
Phosphate of soda.		
Oxalate of ammonia.	Perp. to axis of prism.	Axis of prism.
Hyper-oxymuriate of potash.	Perpendic. to rhomb. plates.	Plane of axis in that diag.
Super-oxalate of potash.		
Super-chromate of potash.		
Crystallized Cheltenham salts.	Axis of prism.	Perp. to axis.
Murio-sulphate of magnesia and iron.	Cleavable diagonal of its square base.	Axis of prism, or other diag.
Benzoate of ammonia.	Perp. to laminæ.	In plane of do.
Benzoic acid.	Perp. to plates.	In plane of plates.
Chromic acid.		
Spermaceti.	Perp. to plates.	In plane of plates.
Boracic acid.	Perp. to hexag. plates.	In plane of plates.
Succinic acid.	Perp. to faces of flat prism.	In plane of these faces.
Super-tartrate of potash.	Perpendicular to axis of prism.	Axis of prism.
Tartrate of potash and antimony.	Perpendicular to axis of prism.	Axis of prism.
Camphor.		
Hydrate of barytes.	Perp. to flat plates.	In ane of plates.
Prussiate of potash.	Perp. to rect. laminæ.	In plane of laminæ.
Mother-of-pearl.	Perp. to laminæ.	In plane of laminæ.
Carbonate of ammonia.	Short diag. of rhomb, and perp. to best cleavage.	Axis of prism, or long diag.
Hyposulphite of lime.	Sir John Herschel, *Edin. Phil. Jour.* vol. i. p. 15.

Polarisation.

Crystals with three axes.

Sect. III.—*On Crystals with three Axes of Double Refraction.*

Having determined the primitive form to which those crystals belong which have *one* and *two* axes of double refraction, Sir David Brewster found that all those crystals which have no resultant axes, or, properly speaking, no double refraction, belonged to that class of primitive forms which have three rectangular axes of form, namely, the *cube*, the *regular octahedron*, and the *rhomboidal dodecahedron*, or to the *tessular* system of Mohs. Since, however, every real axis of double refraction, coincides with a prominent line in the primitive form of the crystal, he conceived that those crystals which had no apparent double refraction had actually *three equal rectangular axes*, the effect of which was to compensate each other at every point of the crystal, or, in other words, to have an infinite number of resultant axes.

In confirmation of these views, our author found various indications of positive and negative doubly refracting structures in *alum, diamond*, &c., as if these equal axes had not exactly compensated each other, either from the three not being perfectly equal, or from their not being placed accurately at right angles to each other.

The following is a list, which might be considerably extended, of the primitive forms of the crystals that have no double refraction.

Primitive form a cube.—Muriate of soda, muriate of potash, muriate of silver.

Primitive form an octahedron.—Diamond, fluor spar, muriate of ammonia, pleonaste, nitrate of lead, sulphate of alumina, soda, alum, ruby copper, spinelle, nitrate of strontian octahedral, nitrate of lead, nitrate of barytes, sulphate of ammonia and chromium, sulphate of ammonia and iron, sulphate of alumina and ammonia.

Primitive form a rhomboidal dodecahedron.—Garnet, blende, sodalite, essonite, helvin, lazulite.

There are some crystals, such as *arseniate of iron, amphigene, analcime, boracite, aplome*, all of which have double refraction, and therefore cannot belong to the tessular system.

Sect. IV.—*On Crystals with Planes of Double Refraction.*

In all the crystals to which we have hitherto referred, the double refraction is related to one or more axes; but Sir David Brewster has found, that in *analcime*, a mineral ranked in the tessular system, there are several planes or sections of the crystal in which there is no double refraction, the double refraction increasing with the distance from these planes, according to a law which will be afterwards mentioned. When the ray is incident in any direction that does not lie in one of these planes, it is separated into two images by double refraction. This is the only substance which is known to possess this remarkable property.

PART VII. ON THE POLARISATION OF LIGHT.

Polarisation of light.

The light emitted from the sun, from a candle, or from any self-luminous body, before it has suffered reflection from, or refraction by, any body, is called *common light*. If we allow a beam of such light to fall upon any refracting or reflecting body, whether transparent or metallic, or to pass by any diffracting body, it will suffer precisely the same changes, whether its upper, its under, its right or its left side, or any other side of the beam, is turned towards the refracting, reflecting, or diffracting body. Hence it follows, that this beam of light has the same properties in all its sides.

Now this is not true of all light. If the preceding beam of common light is reflected at a particular angle, from transparent bodies, or passes obliquely through a number of refracting surfaces, or is transmitted through certain crystals, or suffers total reflexion from the second surfaces of transparent bodies, or from the surface of metals;—in all these cases it has suffered such a change, that it no longer has the same properties in all its sides, but, on the contrary, exhibits distinct and remarkable properties in its different sides, or, what is the same thing, has *polarity*. This beam of common light is therefore said to be *polarised*. The different kinds of polarisation which may thus be impressed upon common light are three, viz. *plane polarisation, circular polarisation*, and *elliptical polarisation*; or the whole of these three kinds of polarisation may be included in the general name of *elliptical polarisation*, which becomes *circular* when the two axes of the ellipsis are equal, and *rectilineal* or *plane* when the minor axis of the ellipse is infinitely small. We shall now proceed to explain the phenomena of these three kinds of polarisation, in their order.

CHAP. I.—ON PLANE POLARISATION.

Plane polarisation.

There are four ways by which common light may be *plane polarised*.

1. By double refraction.
2. By one reflection from transparent bodies.
3. By several refractions through transparent surfaces.
4. By the absorption or dispersion of part of the light.

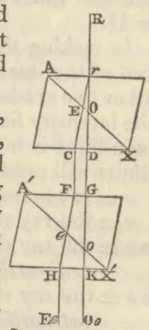
These various processes exhibit many interesting phenomena and laws, which we shall proceed to explain.

Sect. I.—*On the Polarisation of Light by Double Refraction.*

Polarisation by double refraction.

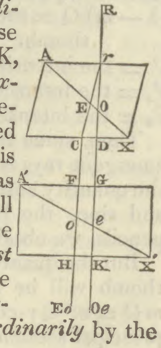
The polarisation of light by the double refraction of Iceland spar was discovered by Huygens. Upon examining the two pencils O *o*, E *e*, fig. 118, formed by double refraction, he found that they had different properties on different sides, and that both of them differed from common light as well as from one another. He discovered this difference in the following manner.

Fig. 130.



Having taken two pieces of Iceland spar, he placed them symmetrically, as in fig. 130, with all the faces of the one parallel to all the faces of the other, A *r* X, A′ G X′ being the principal sections of two rhombs. A ray of common light R *r*, incident upon the first crystal at *r*, is divided into two pencils *r* C, *r* D, O being the ordinary and E the extraordinary ray, as formerly explained. Now the ordinary ray D G, falling upon the second crystal at G, and the extraordinary one CF at F, should have been each subdivided, by double refraction, into two pencils, by that crystal; but they are not, the *ordinary* ray D G being *only* refracted *ordinarily*, and the *extraordinary* ray C F *only extraordinarily*, as seen in the figure, where these rays F H, GK, emerge singly at H and K, the one an *ordinary* and the other an *extraordinary* ray. If the upper rhomb remains fixed while the under one is turned round 90°, so that its principal section is perpendicular to that of the upper one, as shown in fig. 131, the same phenomena will take place, with this difference only, that the ray D G refracted *ordinarily* by the *first* crystal, is refracted *extraordinarily* by the *second*, and the ray C F, refracted *extraordinarily* by the *first* crystal, is refracted *ordinarily* by the *second*.

Fig. 131.



Hence it is manifest, that the ray of common light R *r*, and the two doubly refracted pencils C F, D G, have all

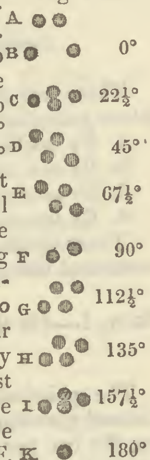
Polarisation.

different properties. For if R r were to fall upon the second rhomb, it would be divided into two pencils; whereas C F and D G refuse to be so divided, and are each refracted in different ways by the second crystal.

Now, in *every other position* of the four rhombs, between the two where their principal sections are *parallel*, or *perpendicular* to one another, the two pencils C F, D G are divided into two pencils, and *four* separate pencils emerge from the second rhomb.

In order to understand the phenomena presented by these *four* pencils, when the second rhomb performs a complete revolution behind the first one, let us suppose that the lower rhomb begins to revolve from the position in fig. 129, which we shall call 0° of azimuth, and in which case we shall have two horizontal pencils H E, K O, fig. 131, whose sections[1] are shown in the annexed figure at B, opposite 0°; A representing the appearance of the aperture through the first rhomb. When the second rhomb has just begun to move out of its position of parallelism to the first, two extremely faint images begin to appear between the other two; and at $22\frac{1}{2}°$ of azimuth they will appear as at C. At 45° of azimuth their intensity will be equal, as at D; at $67\frac{1}{2}°$ the two most distant ones will have become the faintest; and at 90° the four images will be reduced to two, this being the position shown in fig. 130. By continuing to turn the second rhomb, other two faint images start up, which at $112\frac{1}{2}°$ appear as at G; at 135° the four images are equally bright, as at H; at $157\frac{1}{2}°$ the two outermost are the faintest; and at 180° they all coalesce into one bright image, as at K, having twice the brightness of either of those at A or F, and *four* times the brightness of any one of the four at D or H.

Fig. 132.



Malus's law of intensity.

In making the preceding experiment, it will be seen that two of the images gradually increase in brightness, while other two gradually diminish. Malus investigated the law of the intensity for these images, both when the pencil of common light is incident perpendicularly and obliquely. Our limits will permit us to give only the simplest case, making

$o =$ ray refracted *ordinarily* by the *first* rhomb.
$e =$ the ray refracted *extraordinarily* by the *first* rhomb.
$oo =$ the ray refracted *ordinarily* by the *first* rhomb, and *ordinarily* by the *second*.
$oe =$ the ray refracted *ordinarily* by the *first* rhomb, and *extraordinarily* by the *second*.
$ee =$ the ray refracted *extraordinarily* by the *first* rhomb, and *extraordinarily* by the *second*.
$eo =$ the ray refracted *extraordinarily* by the *first* rhomb, and *ordinarily* by the *second*.
$Q =$ the quantity of light contained in the incident ray.
$(1-m)\,Q =$ the quantity of light absorbed by the first rhomb.
$P =$ the intensity of any of the pencils.
$P_o =$ the intensity of the *ordinary* emergent ray.
$P_e =$ the intensity of the *extraordinary* emergent ray.

Then, since the quantity of light contained in the two emergent rays is equal to the incident light diminished by the quantity absorbed, we shall have $Q-(1-m)\,Q = m\,Q$; and since the light is equally divided between the two pencils, we obtain $P_o = \frac{1}{2} m\,Q$, and $P_e = \frac{1}{2} m\,Q$.

But the quantity of light $m\,Q$ which falls upon the second rhomb will be reduced by absorption to $m\,Q-(1-m)\,m\,Q = m^2 Q$; consequently, if a is the angle formed by the principal sections of the two rhombs, we shall have

First pencil, $P_{oo} = \frac{1}{2}\,(m^2\,Q \cos.^2 a)$.
Third pencil, $P_{ee} = \frac{1}{2}\,(m^2\,Q \cos.^2 a)$.
Second pencil, $P_{oe} = \frac{1}{2}\,(m^2\,Q \sin.^2 a)$.
Fourth pencil, $P_{eo} = \frac{1}{2}\,(m^2\,Q \sin.^2 a)$.

When the principal sections of the two rhombs are parallel, then $a = 0$, and $\sin.^2 a = 0$, consequently $P_{oe} = 0$, and $P_{eo} = 0$; that is, *the third and fourth pencils will disappear.*

When, on the contrary, the principal sections are at right angles to one another, $a = 90°$, and $\cos.^2 a = 0$, consequently $P_{oo} = 0$, and $P_{ee} = 0$; that is, *the first and second pencils will disappear.*

When the incident ray is not perpendicular to the surface of the first rhomb, the intensities of the pencils are functions of the angles of incidence and the angle which the ray forms with the principal sections.

All the phenomena above described may be produced by combining any two *positive* and any two *negative* crystals; but if a positive is combined with a negative crystal, the same effects will be produced when the principal sections are at right angles to each other, as when they are parallel in the other cases.

The difference between common and polarised light, as evinced by the phenomena of double refraction, is, that the former may always be divided into two pencils by a doubly-refracting crystal, whereas the latter is not capable of being so divided under certain circumstances.

As the four polarised pencils, when united, as at K, fig. 132, produce a pencil of common light, or rather a pencil which cannot be distinguished from common light, it is highly probable that the Iceland spar, in converting common into polarised light, by refracting it into two pencils, has not communicated to it any new property, but has merely separated it into its two elements, just as a prism separates a pencil of white light into its seven elementary colours by refraction, these colours again forming white light by their reunion.

Sect. II.—*On the Polarisation of Light by Reflection.*

We have already stated, in the history of Optics, the manner in which the celebrated French philosopher Malus discovered the polarisation of light by reflection. Upon repeating his experiments with a variety of opaque and transparent bodies, not metallic, such as glass, water, &c. he found that, *when light was reflected at a particular angle from such bodies, it was polarised exactly like one of the pencils formed by double refraction*, the pencil polarised by reflection having all its properties identically the same with that of the doubly-refracting crystal. Like the latter, it was no longer capable of being divided into *two* pencils by a rhomb of Iceland spar; and as, in the polarisation of light by the double refraction of one crystal, that property depends on the angle formed between the principal sections of the two crystals, as shown in figs. 130 and 131, so, in the present case, the polarisation depends on the angle formed between *the plane of reflection* and that of the principal section of the crystal which polarises the light. In all such phenomena, indeed, as Malus remarks, the *plane of reflection* replaces the plane of the principal section of the crystal.

If we receive the ray polarised by reflection from water at an angle of 52° 45′, upon any crystal having double refraction, it will not be divided into two pencils when the plane of reflection is parallel to the principal section, as if it had been a pencil of common light; but it will be refracted entirely, according to the ordinary law, as if the crystal had lost the power of double refraction. If, on the other

[1] If we place a circular aperture, the size of the little dark circles in fig. 132, at r, the images will have that form.

[Polarisation.] hand, the principal section of the crystal is perpendicular to the plane of reflection, the reflected ray will be refracted wholly, according to the law of extraordinary refraction. In all intermediate positions it will be divided into two rays, according to the same law, and in the same proportions, as if it had acquired its new character by the influence of double refraction.

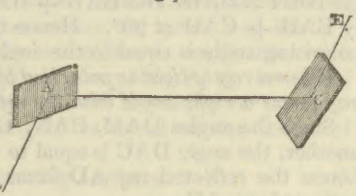
In order to analyse this phenomenon completely, he placed the principal section of a crystal vertically; and after having divided a ray into two by it, he made these two rays fall on the surface of *water*, at an angle of 52° 45′. The ordinary ray was partially reflected, like common light, but *the extraordinary ray penetrated the water wholly, and not a single particle of it was reflected.* When the principal section of the crystal was, on the contrary, perpendicular to the plane of incidence, the *extraordinary* ray was partially reflected, and *the ordinary ray was wholly refracted.*

Malus found the phenomena to be the same for all other transparent bodies, whether solid or fluid; but the angle at which light experienced this modification was in general greater in bodies which refracted light most. Below and above this limit the rays were more or less modified.

This property of reflected light takes place at a different angle for pencils reflected at the *second surfaces* of bodies, and the sine of the angle at the first surface is to the sine of the angle at the second, as the sine of incidence is to the sine of refraction. Hence, in parallel plates, either of glass or other bodies, the two pencils which are reflected in the same directions from both surfaces have equally received this new property, and the light which has received it is said to have been *polarised by reflection.*[1] M. Malus found the same property in black bodies, such as *black marble, ebony*, &c.[2]

Malus next proceeded to study the phenomena when the light R, polarised by one plate of glass A, was reflected from a second plate C, fig. 133, the ray RA being incident on the first plate, and the polarised ray AC on the second plate at an angle of 56°, the polarising angle of glass. In the case shown in the figure, the plane of reflection ACE, in the plate C, is at right angles to the plane of reflection RAC from the first plate, and in this case the reflected pencil CE wholly vanished, all the reflected and polarised light AC having penetrated the glass at C. If we now turn round the plate C from this point, or *zero*, into different azimuths, so that it is always equally inclined to the polarised ray, a small portion of the ray AC will be reflected from C, and this portion will increase till it becomes a maximum, when the plane ACE is parallel to RAC, or in the azimuth of 90°. By continuing to turn the plate C, the reflected ray CE will gradually diminish, and when C has reached the azimuth of 180° its plane of reflection will be perpendicular to that of A, and the reflected ray CE will wholly disappear. In advancing from 180° to 270°, CE will again reach its maximum, and at 360°, when it has returned to its position, as in the figure, it will again return to its minimum.

Fig. 133.



While the reflected pencil CE passes from its *minimum* intensity at 0° and 180°, to its maximum at 90° and 270°, Malus supposes the intensity to vary as the square of the cosine of the angle of azimuth, or of any even power of the cosine. Calling a the angle of azimuth which the plane of the second reflection makes with a plane perpendicular to RAC, I the maximum intensity of the reflected pencil, and P the intensity corresponding to any azimuth a, then $P = I \cos.^2 a$. If we make a equal to 0°, 90°, 180°, and 270°, we shall have, when $a = 0°$, $\cos. a = 1$, $\cos.^2 a = 1$, $\cos.^4 a = 1$, and consequently $P = I$, or the reflected pencil is a maximum. When $a = 90°$, $\cos. a = 0$, $\cos.^2 a = 0$, $\cos.^4 a = 0$, and $F = 0$, that is, the reflected pencil wholly disappears.

It is obvious, from the arrangement of glasses in fig. 132, that, if the light R proceeds from the sky, an observer with his eye placed at E will see a black spot in the part of the sky from which the light R comes, as the whole of the light penetrates the plate C. If the light R comes from a house, the house will disappear if it is at a considerable distance; and by turning round C, the house will have its greatest brightness when the two planes of reflection are parallel. If, in the position when the house was invisible, we breathe upon the plate C, the house will suddenly become visible, and will again disappear when the breath has evaporated. If we now place the plate C at an angle of 52° 45′ to the ray AC, the house will be seen; but if we again breathe upon CC, the house will disappear. The cause of these phenomena is, that by breathing upon C we make the reflecting surface an aqueous one, which refuses to reflect light at an angle of 52° 45′, but reflects it at 56°.

If we place beside each other two sets of reflectors arranged in the manner shown in the figure, C being inclined in the one set 56° to A, and in the other set 52° 45′, and the plates C, C being near each other, we may, by breathing upon each at the same time, exhibit the paradoxical phenomenon of reviving and extinguishing a luminous image by the same breath, or we may appear to breathe at the same time light and darkness.[3]

1. *On the Law of the Polarisation of Light by Reflection.*

After determining the angle at which different bodies polarised light, Malus concluded that "this angle followed neither the order of refractive powers nor that of the dispersive forces, and that it was a property of bodies independent of the other modes of action, which they exercised over light.[4] [Law of polarisation by reflection.]

In repeating the experiments of Malus, Sir David Brewster measured the polarising angles of a greater number of bodies, but experienced many difficulties in connecting them together by a simple law. In some substances the light was not completely polarised at any angle. In others purple and blue light was left at the polarising angles; and in various specimens of glass, different parts of the same surface gave different polarising angles. The first of these phenomena he ascribed to the circumstance that the differently coloured rays of white light were polarised at different angles; and the second he found to arise from changes that had taken place on the surfaces of glass by partial decomposition, owing to the action of the atmosphere. By rejecting those substances where the action of the surface was thus masked or disturbed, he was led to the following general law, that *the index of refraction of any body is the tangent of its angle of polarisation.* [Law of the tangents.]

[1] *Théorie de la Double Refraction*, sect. 48.
[2] *Ibid.* sect. 50.
[3] This experiment was described by Sir David Brewster, in the Edin. Phil. Journal, vol. vii. p. 146. See also his Letters on Natural Magic, p. 125.
[4] *Bull. de Sciences de la Soc. Philos.* Juin 1811, No. 45, tom. ii. p. 294

Polarisation.

The following were the experiments on which this law was founded :—

Names of the Bodies.	Observed Polarising Angles.	Calculated Polarising Angles.
Air	45° or 47°	45° 0′ 32″
Water	52 59[1]	53 11
Fluor spar	54 50	55 9
Obsidian	56 3	56 6
Sulphate of lime	56 28	56 45
Rock crystal	57 22	56 58
Sulphate of barytes	58 29	58 33
Opal-coloured glass	58 1	58 33
Topaz	58 40	58 34
Mother-of-pearl	58 47	58 50
Iceland spar	58 23	58 51
Orange-coloured glass	59 12	59 28
Spinelle ruby	50 6	60 25
Zircon	63 8	63 0
Glass of antimony	64 45	64 30
Sulphur	64 10	63 45
Diamond	68 2	68 1
Chromate of lead	67 42	68 3

Upon repeating these experiments with homogeneous light, our author also found that the angle of polarisation varied with the refrangibility of the light, and that the tangent of the polarising angle was equal to the index of refraction of the light employed.

Hence we are able to explain why, at the maximum polarising angle, a portion of unpolarised light must always remain, and why this portion increases with the refractive and dispersive power of the body. This will be understood from the following table :—

Index of Refraction.	Colour of the Light.	Polarising Angle.	Variation.
Water.			
1·330	Red	53° 4′	0° 15′
1·336	Green, or mean ray	53 11	
1·342	Violet	53 19	
Plate Glass.			
1.515	Red	56 34	0 21
1·525	Green	56 45	
1·535	Violet	56 55	
Oil of Cassia.			
1·597	Red	57 57	1 24
1·642	Green	58 39	
1·687	Violet	59 21	

Now it is obvious, that when the *green* or mean, or most luminous ray, is polarised, and therefore vanishes, neither the red nor the violet has wholly vanished, and consequently a portion of unpolarised light, composed of a portion of these two colours, will still be visible. In oil of cassia the quantity of light is considerable, and is of a fine *blne* colour.

Dr. A. Seebeck's experiments.

So recently as 1830, Dr. A. Seebeck of Berlin has published a series of very accurate and valuable experiments made by an instrument constructed for the purpose, which, if any doubts had existed about the accuracy of the preceding law, were sufficient to remove them. Dr. Seebeck's principal object seems to have been to obtain accurate measures of the polarising angle of different glasses, when the surfaces were newly polished, in order to reconcile the law to that class of bodies in which the deviations had been found to arise from some chemical or mechanical changes produced upon their surface. The following table contains Dr. Seebeck's experiments :—

Names of the Bodies.	Index of Refraction.	Polarising Angles. Observed.	Polarising Angles. Calculated.
Fluor spar, colourless	1·4341	55° 6′·7	55° 6′·7
——— greenish blue	1·4343	55 3·8	55 7·0
Common opal	1·4516	55 29·3	55 26·3
Plate-glass, English, colourless	1·5130	56 36·0	56 32·2
——— colourless	1·5266	56 45·5	56 46·4
Crown-glass, English	1·5321	56 50·2	56 52·0
——— ditto	1·5523	57 12·6	57 12·6
Flint-glass, English	1·5783	57 41·0	57 38·5
——— ditto	1·6206	58 16·6	58 19·4
Pyrope	1·8131	61 4·0	61 7·7
Yellow blende	2·3692	67 8·2	67 7·0

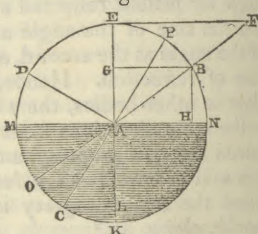
Polarisation.

Upon examining the polarising angles of different specimens of glass at different periods, after the surfaces were polished, Dr. Seebeck confirmed the explanation given by Sir David Brewster, of the variations in their polarising angles.[2]

When a pencil of light is polarised by reflection, the sum of the angles of incidence and refraction is a right angle.

Let MN, fig. 134, be the reflecting surface, and BA a ray of light polarised by reflection in the direction AD, and let AC be the refracted ray. Then, since EF, the tangent of the polarising angle BAE, is equal to m, or the index of refraction, we have, by the law of the sines, $CL = \frac{BG}{m} = \frac{BG}{EF}$. But from the similar triangles ABH, AEF, we have AH, or BG : HB :: EF : rad., and $HB = \frac{BG}{EF}$, consequently $CL = HB$, and the angle BAN = CAK. But EAB + BAN = 90°, consequently EAB + CAK = 90°. Hence the complement of the polarising angle is equal to the angle of refraction.

Fig. 134.



When a ray of light is polarised by reflection, the reflected ray forms a right angle with the refracted ray.

Since the angles DAM, BAN, CAK, are equal to one another, the angle DAC is equal to the right angle MAK; hence the reflected ray AD forms a right angle with the refracted ray AC.

When a pencil of light is incident on the second surface of transparent bodies, at an angle whose cotangent is equal to the index of refraction, the reflected portion will be either wholly polarised, or the quantity of polarised light which it contains will be a maximum.

As the images formed by the first and second surfaces of a transparent plate are simultaneously polarised, this proposition is established by the experimental results in the preceding table.

The angle of polarisation at the second surface of transparent bodies is the complement of the angle of polarisation at the first surface.

As the angle of incidence at the second surface is equal to the angle of refraction at the first surface, and as this latter angle is equal to the complement of the angle of polarisation, it follows that the two polarising angles are complementary to each other.

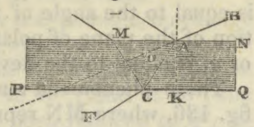
When a ray of light is polarised by reflection from the second surface of transparent bodies, the reflected ray will form a right angle with the refracted ray.

[1] Mean of four observations by Malus, Biot, Arago, and Brewster.
[2] See Poggendorf's *Annalen*, 1830, No. 9, p. 27 ; or Edin. Journ. of Science, N. S. vol. v. p. 99.

Polarisation.

Let AB, fig. 135, be a ray incident at the first surface MN, AD the ray polarised at that surface, AC the ray incident at the second surface PQ, and CM the ray polarised at that surface; then, if CF be the refracted ray, the angle MCF is a right angle. But DAC is a right angle, and on account of the parallelism of MN, PC, and BA, CF, the angle FCP is equal to DAM; but MCP is equal to MAC, hence the whole MCF is equal to the whole DAC, or a right angle.

Fig. 135.



Cor. 1. The ray CM, reflected by the second surface, is at right angles to the ray AB incident on the first surface.

Cor. 2. The internal reflected ray CM forms with the external reflected ray AD, an angle equal to the angle of deviation CAO.

Cor. 3. The ray CF, emerging from the second surface, forms, with the first reflected ray AD, an angle equal to the complement of the angle of deviation.

When a pencil of light is incident upon the separating surface of two media having different indices of refraction m, m′, *it will be polarised at an angle whose tangent is equal to the quotient of the greater index of refraction divided by the lesser, or* $\frac{m}{m'}$, *if* m *exceeds* m′.

This truth is a necessary consequence of the general law, and was also deduced from direct experiment. If the uppermost of the two media is a parallel plate, such as water lying upon a horizontal surface, &c. the separating surface of the two media cannot, at any angle of incidence upon the first surface, completely polarise the incident light, unless the sine of the angle whose tangent is $\frac{m}{m'}$, is, when multiplied by m, less than unity. Thus, in the case of water and glass, the polarising angle is 68° 47′, but no ray incident upon the water, even at 90°, can fall at such an oblique incidence upon the glass as 48° 47′. For sin. 48° 47′ × m' (or the angle of refraction at an incidence of 90°), is = 1·0048. When the upper medium has a higher refractive power than the lower, and lies in a parallel plate upon it, the same law is applicable, with this difference, that the ray is now polarised at the *second surface* of the denser medium, and the angle of polarisation is that whose cotangent is equal to the index of refraction $\frac{m}{m'}$, of the separating surfaces.

Partial polarisation.

In the preceding observations, we have considered only the light which is incident at the polarising angle. It becomes interesting to inquire, what is the condition of the light which is incident at angles above and below the polarising angle. Malus, Arago, Biot, Fresnel, and other distinguished philosophers, considered the light thus reflected as consisting of two pencils, one of which preserved its state of common light, while the other pencil was polarised in the plane of incidence. In the year 1815, however, Sir David Brewster was led, by direct experiments, to a very different opinion, namely, that the pencil of light which was supposed to have preserved its character of common light had *suffered a physical change in its condition, or had acquired in various degrees a character approaching to complete polarisation.* He found, for example, that a pencil of light reflected from glass, either at 62° 30′ or 50° 20′, was so far polarised, that it was wholly polarised by a second reflection at either of these angles; whereas, had the unpolarised part been common light, it could not have been polarised at any angle but 56° 45′. In like manner, he found that *three* reflections at 65° 33′ or 46° 30′, and *four* at 67° 33′ or 43° 51′, polarised the whole pencil; and in general he found *that a ray of light partly polarised by reflection at any angle, will be more and more polarised by every successive reflection in the same plane till its polarisation is complete, whether the reflections are made at angles all above or all below the polarising angle.*

Polarisation.

These views were not acceded to by philosophers, though founded on direct experiment; and, so late as 1825, Sir John Herschel, in discussing the question, gives his decision in favour of the opinion held by the French philosophers.[1] Sir David Brewster was therefore induced to repeat and extend his experiments, and succeeded in establishing his original view of the subject on an impregnable basis. A brief account of these experiments will form the subject of the next section.

2. *On the Motion of the Plane of Polarisation by Reflection.*

Motion of the plane of polarisation.

MM. Fresnel and Arago, and Sir David Brewster, were engaged about the same time in inquiries upon this subject. If we suppose a pencil of polarised light polarised in a plane inclined 45° to a vertical line, and if we reflect it at different angles from a transparent surface in which the plane of reflection is perpendicular to the horizon, the plane of polarisation will be gradually reduced from 45° to 40°, 35°, 30°, 25°, &c. as we diminish the angle of incidence from 90° till we reach the polarising angle, when the plane of polarisation will be inclined 0°, or will be brought into the plane of reflection. At angles less than the polarising angle the plane continues to turn in the same direction, till at 0° it is again inclined 45° to a vertical plane, or to the plane of reflection, having performed a revolution of 90°, the first 45° during the change of incidence from 90° to 56° 45′, and the other 45° from 56° 45′ to 0°.

M. Fresnel represented these changes by the following law: i being the angle of incidence, i' the angle of refraction, x the primitive inclination of the plane of the polarised ray to the plane of reflection, and φ the inclination to which that plane is brought by reflection.

$$\text{Tan.}\,\varphi = \tan.\,x\,\frac{\cos.\,(i+i')}{\cos.\,(i-i')}.$$

When $x = 45°$, tan. $x = 1$, and

$$\tan.\,\varphi = \frac{\cos.\,(i+i')}{\cos.\,(i-i')}.$$

In these formulæ founded on the law of the tangents, $i + i'$ is the supplement of the angle which the reflected ray forms with the refracted ray, while $i - i'$ is the deviation produced by refraction.

The following are the observations with glass and water, with which M. Arago verified the last of these formulæ, in which $x = 45°$.

Glass.

60 0	12 30	11 41	+0 49
50 0	24 0	23 30	+0 30

Our author also made another series of experiments, which confirms the general formula. As $x = 45°$ in the preceding experiments, he wished to observe the law of variation for φ when x varied from 0° to 90°. He took a crystal of quartz with a fine natural face parallel to the axis, and he found, that at an angle of incidence of 75°, and when x was $= 45°$, the inclination of the plane of polarisation to the plane of reflection was 26° 20′. We have therefore $\frac{\cos.(i+i')}{\cos.(i-i')} = \tan.\ 26°\ 20'$, and consequently the general formula becomes $\tan.\ \varphi = \tan.\ x.\ \tan.\ 26°\ 20'$, by which the third column in the following table has been calculated.

Values of x.	Inclination of Plane of Polarisation. Observed.	Calculated.	Difference.
0	0° 0′	0° 0′	0° 0′
10	4 54	4 29	+ 0 25
20	10 0	10 16	— 0 16

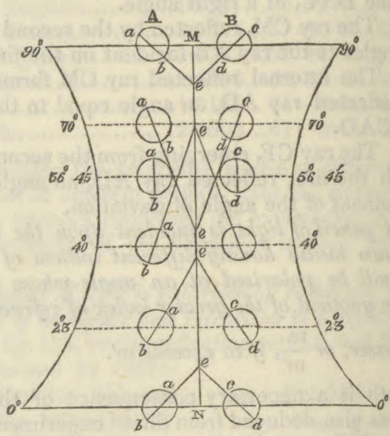
50	30 0	30 40	— 0 40
55	35 30	35 23	+ 0 7
60	40 0	40 45	— 0 45
70	53 0	53 49	— 0 49
80	70 0	70 29	— 0 29
90	90 0	90 0	0 0

It is a curious circumstance, that at an incidence of 45° the deviation produced by refraction, or $i - i'$, is, *in every substance*, the complement of the angle of refraction i' to 45°; and in the action of all substances in turning round the planes of polarisation, at an incidence of 45°, the angle of rotation, when the plane of the polarised ray is $\pm 45°$, is equal to the angle of refraction, while the new inclination of the plane of polarisation to the plane of reflection, or φ, is equal to the deviation $i - i'$.

These phenomena may be represented to the eye as in fig. 136, where MN represents the plane of incidence divided into ninety equal parts, and *ab*, *ab*, *ab* the planes of

Fig. 136.



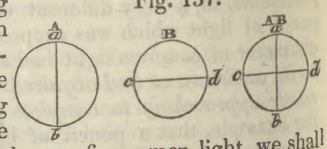
polarisation of the same pencil of light incident at the angles marked upon the curve line. At 90° of incidence, for example, the pencil A has its plane of polarisation inclined 45° to the plane of reflection M; but at 70° the same plane is inclined only 21°, and at 56° it is inclined 0°. At 40° it is inclined 23° in another direction; at 23° about 38°, and at 0° it is inclined 45°.

3. *On the partial Polarisation of Light, and the Law of its Intensity.*

In order to apply these results, Sir David Brewster conceives common light to be composed of two pencils A, B, fig. 136, having their planes of polarisation *ab*, *cd* at right angles to each other, and of equal intensity. Two such pencils united comports itself under all circumstances exactly like common light. We are as much entitled to consider a beam of common light as composed in this manner, as we are to regard white light as composed of seven differently refrangible rays. The prism analyses the one, and doubly-refracting crystals, and the action of transparent surfaces, analyse the other, and common light is recomposed by the two oppositely polarised pencils, as much as white light is recomposed by the union of the seven coloured rays. Considering common light in this manner, Sir David Brewster was led to obtain a complete explanation of the phenomena of polarisation produced by reflexion and refraction.

A beam of common light will be represented as at AB, composed of the two beams A, B, *ab* and *cd* being the planes of polarisation of each of them. In order, however, to analyse the action of a reflecting surface in changing the physical condition of the beam of common light, we shall represent it as in fig. 136, where the planes of polarisation *ab*, *cd* are each inclined 45° to the plane of incidence MN. These two beams are obtained from a rhomb of Iceland spar, upon one of whose surfaces is placed an aperture of the size of A or B, and the rhomb is turned round till its principal section is inclined 45° to the plane of incidence

Fig. 137.



Polarisation.

MN. In this position the double beam or pencil A, B will turn its planes of polarisation as in fig 136.

At an incidence of 90°, or as near it as possible, no change is produced in the pencils A, B, the angle *aec* being still 90°. At an incidence of 80° the angle *aec* is reduced from 90° to 66°; at 70° it has been reduced to 40°; and at 56°, the maximum polarising angle, it has been reduced to 0°, or the planes of polarization *ab*, *cd* being now parallel, or, what is the same thing, the whole of the reflected pencil being polarised in the plane of incidence. Below the polarising angle, the planes *ab*, *cd* continuing to turn in the same direction, are again inclined to each other. At 40° they are inclined 50°; at 23° they are inclined 38°; and at 0°, or a perpendicular incidence, they are again brought back to their primitive inclination of 90°, or the state of common light. The two curves in the figure show the progressive change which takes place in the planes of polarisation, these planes being a tangent to the curve at the incidence which corresponds to any particular part of it.

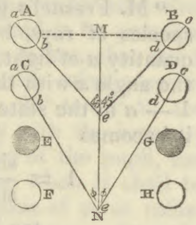
"Such," says Sir David Brewster,[1] "being the action of the reflecting forces upon A and B taken separately, let us now consider them as superposed and forming natural light. At 90° and 0° of incidence, the reflecting force produces no change in the inclination of their axes or planes of polarisation; but at 56° in the case of glass, and 67° 43′ in the case of diamond, the axes of all the particles are brought into a state of parallelism with the plane of reflection; and consequently when the image which they form is viewed by the rhomb of calcareous spar, they will all pass into the ordinary image, and thus prove that they are wholly polarised in the plane of reflection.

"Hence we see that the total polarisation of the reflected pencil at an angle whose tangent is the index of refraction, is effected by turning round the planes of polarisation of one half of the light from right to left, and of the other half from left to right, each through an angle of 45°. Let us now consider what takes place at those angles where the pencil is only partially polarised. At 80°, for example, the angle of the planes *a b*, *c d* is 66°, that is, each plane of polarisation has been turned round in opposite directions from an inclination of 45° to one of 33° with the plane of reflection. The light has therefore suffered a physical change of a very marked kind, constituting now neither natural nor polarised light. It is not natural light, because its planes of polarisation are not rectangular; it is not polarised light, because they are not parallel. It is a pencil of light having the physical character of one half of its rays being polarised at an angle of 66° to the other half. It will now be asked how a pencil thus characterised can exhibit the properties of a partially polarised pencil, that is, of a pencil part of whose light is polarised in the plane of reflection, while the rest retains its condition of natural light. This will be understood by placing the analysing rhomb, with its principal section, in the plane of reflection, and viewing through it the images A and B at 80° of incidence. As the axis of A is inclined 33° to MN or the section of the rhomb, the ordinary image of it will be much brighter than the extraordinary image, the intensity of each being in the ratio of $\cos.^2 \varphi$ to $\sin.^2 \varphi$, φ being the angle of inclination, or 33°, in the present case. In like manner, the ordinary image of B will be in the same ratio brighter than its extraordinary image, that is, by considering A and B in a state of superposition, the extraordinary image of a pencil of light reflected at 80° will be fainter than the ordinary image in the ratio of $\sin.^2 33°$ to $\cos.^2 33°$. But this inequality in the intensity of the two pencils is precisely what would be produced by a compound pencil, part of which is polarised in the plane of reflection, and part of which is common light. When Malus, therefore, and his successors analysed the pencil reflected at 80°, they could not do otherwise than conclude that it was partially polarised, consisting partly of light polarised in the plane of reflection, and partly of natural light. The action of successive reflections, however, afforded a more precise means of analysis, in so far as it proved that the portion of what was deemed natural light had in reality suffered a physical change, which approximated it to the state of polarised light; and we now see that the portion of what was called polarised light was only what may be called apparently polarised; for though it disappears, like polarised light, from the extraordinary image of the analysing prism, yet there is not a single particle of it polarised in the plane of reflection.

"These results lead to conclusions of general importance. The quantity of light which disappears from the extraordinary image, is obviously the quantity of light which is really or apparently polarised at a given angle of incidence; and if we admit the truth of the law of repartition discovered by Malus, and represented by $P_{oo} = P_o \cos.^2 \varphi$, and $P_{oe} = P_o \sin.^2 \varphi$, and as we can determine φ for substances of every refractive power, and for all angles of incidence, we may consider as established the mathematical law which determines the intensity of the polarised pencil, whatever be the nature of the body which reflects it, whatever be the angle at which it is incident, whatever be the number of reflections which it suffers, and whether these reflections are all made from one substance, or partly from one substance and partly from another.

"Let us suppose that a beam of common light composed of two portions A, B (fig. 138) polarised $+ 45°$ and $- 45°$ to the plane of reflection, is incident on a plate of glass at such an angle that the reflected pencil composed of C and D has its planes of polarisation inclined at an angle φ to the plane MN. When a rhomb of calcareous spar has its principal section in the plane MN, it will divide the image C into an extraordinary pencil E and an ordinary one F; and the same will take place with D, G being its extraordinary, and H its ordinary image. If we represent the whole of the reflected pencil, or C + D, by 1, then $C = \frac{1}{2}$, $D = \frac{1}{2}$, $E + F = 1$, and $G + H = 1$. But since the planes of polarisation of C and D are each inclined φ degrees to the principal section of the rhomb, the intensity of the light of the doubly-refracted pencils will be as $\sin.^2 \varphi : \cos.^2 \varphi$; that is, the intensity of E will be $\frac{1}{2} \sin.^2 \varphi$, and that of F, $\frac{1}{2} \cos.^2 \varphi$. Hence it follows that the difference of these pencils, or $\frac{1}{2} \sin.^2 \varphi - \frac{1}{2} \cos.^2 \varphi$, will express the quantity of light which has passed from the extraordinary image E into the ordinary one F; that is, the quantity of light apparently polarised in the plane of reflection MN. But as the same is true of the pencil D, we have $2 (\frac{1}{2} \sin.^2 \varphi - \frac{1}{2} \cos.^2 \varphi)$ or $\sin.^2 \varphi - \cos.^2 \varphi$ for the whole of the polarised light in a pencil of common light C + D. Hence, since $\sin.^2 \varphi + \cos.^2 \varphi = 1$, and $\cos.^2 \varphi = 1 - \sin.^2 \varphi$, we have for the whole quantity of polarised light

Fig. 138.



$$Q = 1 - 2 \sin.^2 \varphi.$$

$$\text{But } \tan. \varphi = \tan. x \frac{\cos. (i + i')}{\cos. (i - i')}$$

$$\text{And as } \tan.^2 \varphi = \frac{\sin.^2 \varphi}{\cos.^2 \varphi}, \text{ and } \sin.^2 \varphi + \cos.^2 \varphi = 1,$$

we have the quotient and the sum of the quantities $\sin.^2 \varphi$ and $\cos.^2 \varphi$, by which we obtain

[1] Phil. Trans. 1830, p. 71.

Polarisation.

$$\sin^2 \phi = \cfrac{1}{\cfrac{1}{\left(\tan. x \dfrac{\cos. (i + i')}{\cos. (i - i')}\right)^2 + 1}}$$

$$= \frac{\left(\tan. x \dfrac{\cos. (i + i')}{\cos. (i - i')}\right)^2}{1 + \left(\tan. x \dfrac{\cos (i + i')}{\cos. (i - i')}\right)^2}$$

$$\text{That is, } Q = 1 - 2 \frac{\left(\tan. x \dfrac{\cos. (i + i')}{\cos. (i - i')}\right)^2}{1 + \left(\tan. x \dfrac{\cos. (i + i')}{\cos. (i - i')}\right)^2}$$

"As the quantity of reflected light is here supposed to be 1, we may obtain an expression of Q in terms of the incident light, by adopting the formula of Fresnel for the intensity of a reflected ray. Thus,

$$Q = \tfrac{1}{2} \left(\frac{\sin.^2 (i - i')}{\sin.^2 (i + i')} + \frac{\tan.^2 (i - i')}{\tan.^2 (i + i')}\right)$$

$$\times \left(1 - 2 \frac{\left(\dfrac{\cos. (i + i')}{\cos. (i - i')}\right)^2}{1 + \left(\dfrac{\cos. (i + i')}{\cos. (i - i')}\right)^2}\right).$$

"As $\tan. x = 1$ in common light, it is omitted in the preceding formula.

"This formula may be adapted to partially polarised rays, that is, to light reflected at any angle different from the angle of maximum polarisation, provided we can obtain an expression for the quantity of reflected light.

"M. Fresnel's general formula has been adapted to this species of rays, by considering them as consisting of a quantity a of light completely polarised in a plane making the angle x with that of incidence, and of another quantity $1 - a$ in the state of natural light. Upon this principle it becomes

$$1 = \frac{\sin.^2 (i - i')}{\sin.^2 (i + i')} \cdot \frac{1 + a \cos.^2 x}{2}$$
$$+ \frac{\tan.^2 (i - i')}{\tan.^2 (i - i')} \cdot \frac{1 - a \cos.^2 x}{2}.$$

"But as we have proved that partially polarised rays are rays whose planes of polarisation form an angle of $2x$ with one another as already explained, x being greater or less than 45°, we obtain a simpler expression for the intensity of the reflected pencil, viz. the very same as that for polarised light.

$$1 = \frac{\sin.^2 (i - i')}{\sin.^2 (i + i')} \cos.^2 x + \frac{\tan.^2 (i - i')}{\tan.^2 (i + i')} \sin.^2 x.$$

Hence we have

$$Q = \left(\frac{\sin.^2 (i - i')}{\sin.^2 (i + i')} \cos.^2 x + \frac{\tan.^2 (i - i')}{\tan.^2 (i + i')} \sin.^2 x\right),$$

$$\left(1 - 2 \frac{\left(\tan. x \dfrac{\cos. (i + i')}{\cos. (i - i')}\right)^2}{+\left(\tan. x \dfrac{\cos. (i + i')}{\cos. (i - i')}\right)^2}\right).$$

"This formula is equally applicable to a single pencil of polarised light of the same intensity as the pencil of partially polarised light. In all these cases it expresses the quantity of light really or apparently polarised in the plane of reflection.

"In order to show the quantity of light polarised at different angles of incidence, I have computed the following table for common light, and suited to glass in which $m = 1{\cdot}525$.

Angle of Incidence i.	Angle of Refraction i'.	Inclination of Plane of Polarisation to Plane of Reflection, ϕ.	Quantity of Light Reflected out of 1000 Rays.	Quantity of Polarised Light Q.	Ratio of Polarised to Reflected Light.

"As the preceding formula is deduced from principles which have been either established by experiment or confirmed by it, it may be expected to harmonize with the results of observation. At all the limits where the pencil is either wholly polarised or not polarised at all, it of course corresponds with experiment; but though, in so far as I know, there have been no absolute measures taken of the quantity of polarised light at different incidences, yet we are fortunately in possession of a set of experiments by M. Arago, who has ascertained the angles above and below the polarising angle at which glass and water polarise the same proportion of light. In no case has he measured the absolute quantity of the polarised rays; but the comparison of the values of Q at those angles at which he found them in equal proportions, will afford a test of the accuracy of the formula. This comparison is shown in the following table, in which column 1 contains the angles at which the reflecting surface polarises equal proportions of light; column 2 the values of ϕ, or the inclination of the planes of polarisation; and column 3 the intensities of the polarised light computed from the formula.

	Angles of Incidence.	Inclination of Planes of Polarisation to MN, or ϕ.	Proportion of Polarised Light, or Q.
Glass: No. 1.	82° 48′	37° 33′	·2572
	24 18	37 21	·2637
No. 2.	82 5	36 47	·2828
	26 6	36 0	·3090
No. 3.	78 20	32 38	·4186
	29 42	33 1	·4064
Water: No. 4.	86 31	41 54	·1080
	16 12	41 27	·1236

"The agreement of the formula with experiments made with as great accuracy as the subject will admit, must be allowed to be very satisfactory. The differences are within the limits of the errors of observation, as appears from the following table:

	Deviations from Experiment.	Part of the whole Light.
Glass: No. 1.	0·0065	$\frac{1}{154}$
No. 2.	0·0262	$\frac{1}{38}$
No. 3.	0·0122	$\frac{1}{82}$
Water: No. 4.	0·0156	$\frac{1}{64}$

"M. Arago has concluded, from the experiments above stated, that equal proportions of light are polarised at equal angular distances from the angle of complete polarisation. Thus, in glass No. 1, the mean of 82° 48′ and 24° 18′ is 53° 33′, which does not differ widely from the maximum polarising angle, or 55°, which M. Arago considers as the maximum polarising angle of the glass.[1] In order to compare this principle with the formula, I found, that in water No. 4, the angle which polarises almost exactly the same proportion of light as the angle of 86° 31′, is 15° 10′, the value of φ being 41° 54′ at both these angles; but the mean of these is 50° 50′ in place of 53° 11′, so that the rule of M. Arago cannot be regarded as correct, and cannot therefore be employed, as he proposes, to determine the angle of complete polarisation."[2]

4. *On the Law of the Polarisation of Light by successive Reflections.*

We come now to show the application of the preceding law of intensity to the phenomena of the polarisation of light by successive reflections.

"When a pencil of common light," says Sir David Brewster,[3] "has been reflected from a transparent surface, at an angle of 61° 3′, for example, it has experienced such a physical change that its planes of polarisation form an angle of 6° 45′ each with the plane of reflection. When it is incident on another similar surface at the same angle, it is no longer common light, in which $x = 45°$, but it is partially polarised light, in which $x = 6°$ 45′. In computing, therefore, the effect of the second reflection, we must take the general formula $\tan. \varphi = \tan. x \left(\frac{\cos. (i + i')}{\cos. (i - i')}\right)$; but as the value of x is always in the same ratio to the value of φ, however great be the number of reflections, we have $\tan. \theta = \tan.^n \varphi$ for the inclination θ to the plane of reflection produced by any number of reflections n, φ being the inclination for one reflection. Hence, when θ is given by observation, we have $\tan. \varphi = \sqrt[n]{\theta}$. The formula for any number n of reflections is therefore $\tan. \theta = \left(\frac{\cos. (i + i')}{\cos. (i + i')}\right)^n$. It is evident that θ never can become equal to 0°; that is, that the pencil cannot be so completely polarised by any number of reflections at angles different from the polarising angle, as it is by a single reflection at the polarising angle; but we shall see that the polarisation is sensibly complete, in consequence of the near approximation of θ to 0°.

"I found, for example, that light was polarised by two reflections from glass at an angle of 61° 3′, and 60° 28′ by another observation. Now, in these cases, we have

	θ after 1st Reflection.	θ after 2d Reflection.	Quantity of Unpolarised Light.
two reflections at 61° 3′	6° 45′	0° 47	0·00037
60 28	5 38	0 33	0·00018

The quantity of unpolarised light is here so small as to be quite unappreciable with ordinary lights.

"In like manner, I found that light was completely polarised by five reflections at 70°. Hence, by the formula, we have

	Values of θ.	Unpolarised Light.
1 reflection at 70°	20° 0′	0·23392
2	7 32	0·03432
3	2 45	0·00460
4	1 0	0·00060
5	0 22	0·00008

The quantity of unpolarised light is here also unappreciable after the fifth reflection.

In another experiment it was found that light was wholly polarised by the separating surface of glass and water at the following angles:

	Values of θ.	Unpolarised Light.
By 2 reflections at 44° 51′	0° 56′	0·0005
By 3 42 27	0 26	0·0001

"In all these cases the successive reflections were made at the same angle; but the formula is equally applicable to reflections at different angles,—

"1. When both the angles are greater than the polarising angle,—

	θ.	Unpolarised Light.
1 reflection at 58° 2′, and 1 at 67° 2′	0° 34′	0·0002

"2. When one of the angles is above and the other below the polarising angle,—

	θ.	Unpolarised Light.
1 reflection at 53°, and 1 at 58° 2′	0° 12′	0·000024

This experiment requires a very intense light; for I find in my journal that the light of a candle is polarised at 53° and 78°.

"In reflections at different angles, the formula becomes $\tan. = \frac{\cos. (i + i')}{\cos. (i - i')} \times \frac{\cos. (\mathrm{I} + \mathrm{I}')}{\cos. (\mathrm{I} + \mathrm{I}')}$, I and i being the angles of incidence. In like manner, if a, b, c, d, e, &c. are the values of φ or θ for each reflection, or rather for each angle of incidence, we shall have the final angle, or $\tan. \theta = \tan. a \times \tan. b \times \tan. c \times \tan. d$, &c.

"It is scarcely necessary to inform the reader, that when a pencil of light reflected at 58° 2′ is said to be polarized by another reflection at 67° 2′, it only means, that this is the angle at which complete polarisation takes place in diminishing the angle gradually from 90° to 67° 2′, and that even this angle of 67° 2′ will vary with the intensity of the original pencil, with the opening of the pupil, and with the sensibility of the retina. But when it shall be determined experimentally at what value of φ, or rather at what value of Q, the light entirely disappears from the extraordinary image, we shall be able, by inverting the formula, to ascertain the exact number of reflections by which a given pencil of light shall be wholly polarised.

"As the value of Q depends on the relation of i and i', that is, on the index of refraction, and as this index varies for the different colours of the spectrum, it is obvious that Q will have different values for these different colours. The consequence of this must be, that in bodies of high dispersive powers, the unpolarised light which remains in the extraordinary image, and also the light which forms the ordinary image, must be coloured at all incidences; the colours being most distinct near the maximum polarising angle. This necessary result of the formula was found to be experimentally true in oil of cassia, and various highly dispersive bodies. In realgar, for example, φ is $= 0$ at an angle of 69° 0′ for blue light, at 68° 37′ for green light, and at 66° 49′ for red light. Hence there can be no angle of complete polarisation for white light, which was also found to be the case by experiment; and as Q must at different angles of incidence have different values for the different rays, the unpolarised light must be composed of a certain portion of each different colour, which may be easily determined by the formula.

"Such are the laws which regulate the polarisation of

[1] Hence we have assumed $m = 1·428$, the tangent of 55°, in the preceding calculations.
[2] It is obvious that the rule can only be true when $m = 1·000$; so that its error increases with the refractive power.
[3] Phil. Trans. 1830, p. 80.

Polarisation.

light by reflection from the first surfaces of bodies that are not metallic. The very same laws are applicable to their second surfaces, provided that the incident light has not suffered previous or subsequent refraction from the first surface. The sine of the angle at which φ or Q has a certain value by reflection from the second surface, is to the sine of the angle at which they have the same value at the first surface, as unity is to the index of refraction. Hence φ and Q may be determined by the preceding formulæ after any number of reflections, even if some of the reflections are made from the first surface of one body and the second surface of another."

Sect. III.—*On the Polarisation of Light by Refraction.*

We have already seen that the polarisation of light by refraction was discovered by independent observations by Malus, Biot, and Brewster; but the priority of discovery belongs to Malus, who, from various observations, arrived at the following conclusion: "When a ray of light falls upon a plate of glass at an angle of 54° 35′, all the light which it reflects is polarised in one direction. The light which traverses the glass is composed, 1*st*, of a quantity of light polarised in a direction opposite to that which is reflected, and proportional to it; and, 2*dly*, of another portion not modified, and which preserves the character of direct light."

Sir David Brewster made analogous experiments with thin films of glass, films of mica, folds of gold-beaters' skin, and films of gold leaf; but he occupied himself chiefly in determining the law of the phenomena depending on the number of plates through which the light was transmitted, and found *that the number of plates which polarise a maximum of light by transmission at different angles of incidence, are to one another as the co-tangents of the angles of incidence.*

In determining this law, our author employed forty-seven plates of crown-glass, each about three inches long and one broad, and with these he obtained the following results:—

Number of Plates in each Parcel.	Angles of Incidence at which Light is Polarised, by Calculation.	Angles of Incidence at which Light is Polarised, by Experiment.	Differences between the Calculated and Observed Angles.
8	79° 11′	78° 52′ [1]	0 19′ —
10	76 33	76 24	0 9 —
12	74 0	74 2	0 2 +
14	71 30	72 15	0 45 +
16	69 4	69 40	0 36 +
18	66 43	66 43	0 0
21	63 21	63 39	0 18 +
24	60 8	61 0	0 52 +
27	57 10	56 58	0 12 —

39	47 1	46 50	0 11 —
41	45 35	45 49	0 14 +
44	43 34	44 0	0 26 +
47	41 41	42 0	0 19 +
100	22 42		
200	11 49		
500	4 47		
1,000	2 24		
2,000	1 12		
4,000	0 36		
14,000	0 1		
8,640,000	0 0 1″		

[1] This result was obtained by a parcel of plates of parallel glass.

If n, n', therefore, represent the number of plates in any two parcels, and φ, φ the angles at which the pencil was polarised, we have

$$n : n' = \text{cotan. } \varphi : \text{cotan. } \varphi', \text{ and}$$
$$n \times \text{tan. } \varphi = n' \times \text{tan. } \varphi'.$$

That is, the *number of plates in any parcel, multiplied by the tangent of the angle at which it polarises light, is a constant quantity.* From a great number of observations made with a parcel of eighteen plates, our author found the constant quantity for crown-glass to be 41·84 when the light was that of a good wax-candle placed at the distance of about twelve feet, so that we have

$$\text{tan. } \varphi = \frac{41{\cdot}84}{n};$$

that is, divide the constant quantity by any given number of plates, and the quotient will be the natural tangent of the angle at which that number will polarise a pencil of light.

In this way the *second* column of the table, which differs very little from the observed column, was computed.

From these experiments our author drew the same conclusion as in the case of reflection, respecting the state of what Malus calls the unpolarised light, namely, that it had suffered a physical change; and he also showed that light could be polarised by successive refractions, each refraction bringing it gradually nearer and nearer to the state of complete polarisation.

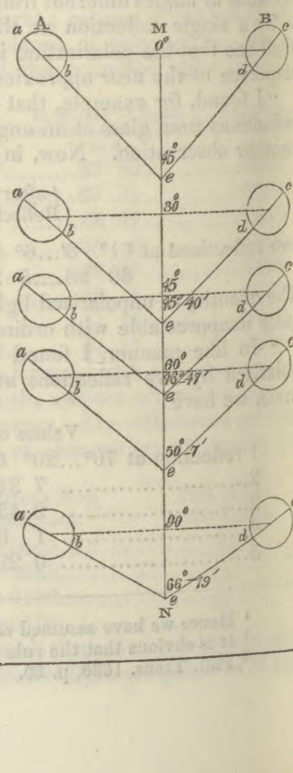
1. *On the Motion of the Planes of Polarisation by Refraction.*

The first, and we believe the only, experiments that have been made on this subject, were those of Sir David Brewster;[1] and we shall therefore give an account of his researches in his own words, abridging it as much as possible.

"If we take a plate of glass, deviating so slightly from parallelism between it faces as to throw aside from the direct transmitted image of a luminous body the faint images formed by reflection between its inner surfaces, we shall obtain, even at the greatest obliquities, a pencil of light free of all admixture of reflected light.

"Let this plate be placed upon a divided circle, so that we can observe through it two luminous discs of polarised light A, B (fig. 139) formed by double refraction, and having their planes of polarisation inclined + 45° and — 45° to the plane of refraction. At a perpendicular incidence, the inclination of the planes of polarisation will suffer no change; but at an incidence of 30° they will be turned round 40′, so that their inclination to MN or the angle *aec* will be 45° 40′. At 45° their inclination will be 46° 47′. At 60° it will be 50° 7′; and it will increase gradually to 90°, where it becomes 66° 19′. Hence the maximum change produced by a single plate of glass upon the planes of polarisation is 66° 19′—45° = 21° 19′, an effect exactly equal to

Fig. 139.



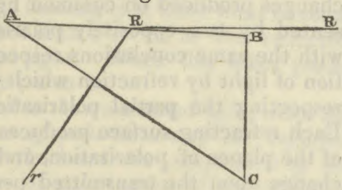
[1] Phil. Trans. 1830, p. 133.

what is produced by reflection at angles of 39° or 70°. It is remarkable, however, *that this change is made in the opposite direction, the planes of polarisation now approaching to coincidence in a plane at right angles to that of reflection* ; a difference which might have been expected from the opposite character of the resulting polarisation.

"In this experiment the action of the two surfaces is developed in succession, so that we cannot deduce from the maximum rotation of 21° 19′, the real action of the first, or of a single surface, which must be obviously more than half of the action of the two surfaces, because the planes of polarisation have been widened before they undergo the action of the second surface.

"In order to obtain the rotation due to a single surface, I took a prism of glass ABC, having such an angle BAC, that a ray RR, incident as obliquely as possible, should emerge in a direction Rr perpendicular to the surface AC. I took care that this prism was well annealed, and I caused the refraction to be performed as near as possible to the vertex A, where the glass was thinnest, and consequently most free from the influence of any polarising structure. In this way I obtained the following measures.

Fig. 140.



Glass.

Angles of Incidence.	Inclination of Planes *ab, cd*, to the Plane of Reflection.	Rotation of Plane for one Surface.
87° 38′	54° 15′	9° 15′
54 50	47 25	2 25
32 20	45 22	0 22

"I next made the following experiments with two kinds of glass, the one a piece of parallel plate-glass, and the other a piece of very thin crown. The latter had the advantage of separating the reflected from the transmitted light.

	Plate Glass.		*Crown Glass.*	
Incidence.	Inclination.	Rotation for two Surfaces.	Inclination.	Rotation for two Surfaces.
0°	45° 0′	0° 0′	45° 0′	0° 0′
40	47 28	2 28	47 18	2 18
55	49 35	4 35	49 19	4 19
67	52 53	7 53	58 16	7 16
80	58 53	13 53	58 42	13 42
86½	61 16	16 16	61 0	16 0

"In order to ascertain the influence of refractive power, I stretched a film of soapy water across a rectangular frame of copper wire, and obtained the following measures:

Water.

Incidence.	Inclination.	Rotation.
85°	54° 17′	9° 17′

Metalline Glass.

0	45 0	0 0
20	45 42	0 42
30	46 50	1 50
40	48 0	3 0
55	51 12	6 12
80	62 32	17 32

"From a comparison of these results, it is manifest that *the rotation increases with the refractive power.*

"In examining the effects produced at different incidences, it is obvious that the rotation R varies with the deviation of the refracted ray; that is, with $i - i'$. Hence I have been led to express the inclination φ of the planes of polarisation to the plane of refraction and the rotation by the formulæ

$$\cot. \varphi = \cos. (i - i'), \qquad R = \varphi - 45°.$$

"This formula represents the experiments so accurately, that when the rhomb of calcareous spar is set to the calculated angle of inclination, the extraordinary image is completely invisible.

"The above expression is of course suited only to the case where the inclination x of the planes of polarisation *ab, cd* (fig. 139), is 45°; but when this is not the case, the general expression is

$$\cot. \theta = \cot. x \cos. (i - i').$$

"When the light passes through a second surface, as in a single plate of glass, the value of x for the second surface is evidently the value of φ after the first refraction; or, in general, calling θ the inclination after any number n of refractions, and φ the inclination after one refraction,

$$\cot. \theta = (\cot. \varphi)^n.$$

"When θ is given by observation we have

$$\cot. \varphi = \sqrt[n]{\cot. \theta}.$$

"The general formula for any inclination x and any number n of refractions is

$$\cot. \theta = \big(\cot. x \cos. (i - i')\big)^n, \text{ and}$$

$$\cot. \varphi = \sqrt[n]{\cot. x \cos. (i - i')}.$$

"And when $x = 45$ and $\cot. x = 1$, as in common light,

$$\cot. \theta = \big(\cos. (i - i')\big)^n,$$

$$\cot. \varphi = \sqrt[n]{\cos. (i - i')}.$$

"As the term $\big(\cos. (i - i')\big)^n$ can never become equal to 0, the planes of polarisation can never be brought into a state of coincidence in a plane perpendicular to that of reflection.

"In order to compare the formula with experiment, I took a plate of well-annealed glass, which at all incidences separates the reflected from the transmitted rays, and in which m was nearly 1·510, and I obtained the following results:

Angles of Incidence.	Angles of Refraction.	Rotation observed.	Inclination observed.	Inclination calculated.	Difference.
0°	0° 0′	0° 0′	45° 0′	45° 0′	
10	6 36½	0 13	45 13	45 6	+0° 7′
20	13 5	0 27	45 27	45 25	+0 2
25	16 15	0 32	45 32	45 40	−0 8
30	19 20	0 40	45 40	46 0	−0 20
35	22 19	1 12	46 12	46 25	−0 13
40	25 10	1 30	46 30	46 56	−0 26
45	27 55	1 42	46 47	47 34	+0 47
50	30 29	2 48	47 42	48 24	−0 42
55	33 52	3 54	48 54	48 59	−0 5
60	35 0	5 7	50 7	50 36	−0 29
65	36 53	6 48	51 48	52 7	−0 19
70	38 29	8 7	53 7	53 59	−0 52
75	39 45	9 55	54 55	56 18	−1 23
80	40 42	12 10	57 10	59 5	−1 55
85	41 19	15 45	60 45	62 24	−1 39
86	41 21	16 39	61 39	63 9	−1 30
90	41 28			66 19	

"The last column but one of the table was calculated by the formula

$$\cot. \theta = \cos. \big(\cos. (i - i')\big)^2,$$

n being in this case 2. The errors, however, being almost all negative, I suspected that there was an error of adjustment in the apparatus; and upon repeating the experiment at 80°, the point of maximum error, I found that the inclination was fully 58° 40′, giving a difference only of 25 in place of 1° 55′.

"In these experiments $x = 45°$ and $\cot. x = 1$; but in order to try the general formula when x varied from 0° to 90°, I took the case where the angle of incidence was 80°,

Polarisation.

and $\varphi = 58° 40'$ when $x = 45°$. The following were the results.

Values of x.	Inclination observed.	Inclination calculated.	Difference.
0°	0° 0′	0° 0′	0° 0′
$2\frac{1}{2}$	7 10	7 20	— 0 10
5	9 40	8 19	+ 1 21
10	17 10	16 25	+ 0 45
15	24 42	24 6	+ 0 36
20	32 30	31 19	+ 1 11
25	39 15	37 54	+ 1 21
30	44 10	43 57	+ 0 13
35	49 38	49 28	+ 0 10
40	54 36	54 31	+ 0 5
45	58 40	59 5	— 0 25
50	63 10	63 19	— 0 9
55	66 58	67 15	— 0 17
60	70 18	70 56	— 0 38
65	74 8	74 24	— 0 16
70	76 56	77 42	— 0 46
75	79 20	80 53	— 1 33
80	83 23	83 58	— 0 35
85	86 23	86 0	+ 0 23
90	90 0	90 0	0 0

"The last column but one was calculated by the formula $\cot. \theta = \cot. x \,.\, (\cot. 58° 40')^2$.

"In determining the quantity of polarised light in the refracted pencil, we must follow the method already explained for the reflected ray, *mutatis mutandis.* The principal section of the analysing rhomb being now supposed to be placed in a plane perpendicular to the plane of reflection, the quantity of light Q′ polarised in that plane will be

$$Q' = 1 - 2 \cos.^2 \varphi,$$

the quantity of transmitted light being unity. But

$$\cot. \varphi = \cot. x \cos. (i - i'),$$

and as $\cot. \varphi = \frac{\cos.^2 \varphi}{\sin.^2 \varphi}$, and $\sin.^2 \varphi + \cos.^2 \varphi = 1$, we have the quotient and the sum of $\sin.^2 \varphi$ and $\cos.^2 \varphi$ to find them.

$$\text{Hence } \cos.^2 \varphi = \frac{(\cot. x \cos. (i - i'))^2}{1 + (\cot. x \cos. (i - i'))^2};$$

and by substituting this for $\cos.^2 \varphi$ in the former equation, it becomes

$$Q' = 1 - 2 \frac{(\cot. x \cos. (i - i'))^2}{1 + (\cot. x. \cos. (i - i'))^2}.$$

"Now since, by Fresnel's formula, the quantity of reflected light is

$$R = \tfrac{1}{2} \left(\frac{\sin.^2 (i - i')}{\sin.^2 (i + i')} + \frac{\tan.^2 (i - i')}{\tan.^2 (i + i')} \right),$$

the quantity of transmitted light T will be

$$T = 1 - \tfrac{1}{2} \left(\frac{\sin.^2 (i - i')}{\sin.^2 (i + i')} + \frac{\tan.^2 (i - i')}{\tan.^2 (i + i')} \right).$$

$$\text{Hence } Q' = \left(1 - \tfrac{1}{2} \left(\frac{\sin.^2 (i - i')}{\sin.^2 (i + i')} + \frac{\tan.^2 (i - i')}{\tan.^2 (i + i')} \right) \right)$$

$$\left(1 - 2 \frac{(\cos. (i - i'))^2}{1 + (\cos. (i - i'))^2} \right).$$

"This formula is applicable to common light, in which $\cot. x = 1$ disappears from the equation; but, on the same principles which we have explained in a preceding paper, it becomes for partially polarised rays and for polarised light,

$$Q' = \left(1 - \tfrac{1}{2} \left(\frac{\sin.^2 (i - i')}{\sin.^2 (i + i')} \cos.^2 x + \frac{\tan.^2 (i - i')}{\tan.^2 (i + i')} \sin.^2 x \right) \right)$$

$$\left(1 - 2 \frac{(\cot. x \cos. (i - i'))^2}{1 + (\cot. x \cos. (i - i'))^2} \right).$$

"In all these cases the formula expresses the quantity of light really or apparently polarised in the plane of refraction.

"As the planes of polarisation of a pencil polarised + 45° and — 45° cannot be brought into a state of coincidence by refraction, the quantity of light polarised by refraction can never be mathematically equal to the whole of the transmitted pencil, however numerous be the refractions which it undergoes; or, what is the same thing, refraction cannot produce rays truly polarised, that is, with their planes of polarisation parallel."

2. *On the partial Polarisation of Light by one or more Refractions.*

"The analysis given in the preceding paragraphs, of the changes produced on common light, considered as represented by two oppositely polarised pencils, furnishes us with the same conclusions respecting the partial polarisation of light by refraction which we have already deduced respecting the partial polarisation of light by reflection. Each refracting surface produces a change in the position of the planes of polarisation, and consequently a physical change upon the transmitted pencil by which it has approached to the state of complete polarisation.

"This position I shall illustrate by applying the formula to the experiments in a preceding page.

"According to the first of these, the light of a wax-candle at the distance of ten or twelve feet is wholly polarised by eight plates or sixteen surfaces of parallel plate-glass at an angle of 78° 52′. Now I have ascertained that a pencil of light of this intensity will disappear from the extraordinary image, or appear to be completely polarised, provided its planes of polarisation do not form an angle of less than $88\frac{3}{4}°$ with the plane of refraction for a moderate number of plates, or $88\frac{1}{2}°$ for a considerable number of plates, the difference arising from the great diminution of the light in passing through the substance of the glass. In the present case the formula gives

$$\cot. \theta = (\cos. (i - i'))^{16} \text{ and } \theta = 88° 50';$$

so that the light should appear to be completely polarised, as it was found to be.

"At an angle of 61° 0′ the pencil was polarised by twenty-four plates or forty-eight surfaces. Here

$$\cot. \theta = (\cos. (i - i'))^{48} = 89° 36'.$$

"At an angle of 43° 34′ the light was polarised by forty-seven plates or ninety-four surfaces. Here

$$\cot. \theta = (\cos. (i - i'))^{94} \text{ and } \theta = 88° 27'.$$

"It is needless to carry this comparison any further; but it may be interesting to ascertain by the formula the smallest number of refractions which will produce complete polarisation. In this case the angle of incidence must be 90°.

"Hence, $\varphi = 56° 29'$ and $(\cos. (i - i'))^9$ gives 88° 36′, and $(\cos. (i - i'))^{10}$ 89° 4′; that is, the polarisation will be nearly complete by the most oblique transmission through four and a half plates or nine surfaces, and will be perfectly complete through five plates or ten surfaces."

Sect. IV.—*Comparison of the Laws of Intensity for Light polarised by Reflection and Refraction.*

"Having obtained formulæ for the quantity of light polarised by refraction and reflection, it becomes a point of great importance to compare the results which they furnish. Calling R the reflected light, these formulæ become

$$Q = R\left(1 - 2\frac{\left(\frac{\cos.(i+i')}{\cos.(i-i')}\right)^2}{1+\left(\frac{\cos.(i+i')}{\cos.(i-i')}\right)^2}\right), \text{ and}$$

$$Q' = 1 - R\left(1 - 2\frac{(\cos.(i-i'))^2}{\varphi + (\cos.(i-i'))^2}\right).$$

"But these two quantities are equal, and hencc we obtain the important general law, that,—*At the first surface of all bodies, and at all angles of incidence, the quantity of light polarised by refraction is equal to the quantity polarised by reflection. I have said 'of all bodies,' because the law is equally applicable to the surfaces of crystallized and metallic bodies, though the action of their first surface is masked or modified by other causes.*

"It is obvious from the formula that there must be some angle of incidence where $R = 1 - R$, or the reflected equal to the transmitted light. When this takes place, we have $\sin.^2\varphi = \cos.^2\varphi'$; that is,

"*The reflected is equal to the transmitted light, when the inclination of the planes of polarisation of the reflected pencil to the plane of reflection, is the complement of the inclination of the planes of polarisation of the refracted pencil to the same plane;* or, if we refer the inclination of the planes to the two rectangular planes into which the planes of polarisation are brought,—*The reflected will be equal to the transmitted light when the inclination of the planes of polarisation of the reflected pencil to the plane of reflection is equal to the inclination of the plane of polarisation of the refracted pencil to a plane perpendicular to the plane of reflection.*

"In the following table, the inclination of the planes of polarisation of the reflected and the refracted pencil, and the quantities of light reflected, transmitted, and polarised, at all angles of incidence upon glass, m being equal to 1·525, and the incident light = 1000, are given:

Angles of Incidence, i.	Angles of Refraction, i'.	Inclination of Plane of Polarisation of the Reflected Light, φ'.	Inclination of Plane of Polarisation of the Refracted Light, φ.	Quantity of Light Reflected, R.	Quantity of Light Transmitted, 1 — R.	Quantity of Light Polarised, Q.

"It is obvious, from a consideration of the principle of the formula for reflected light, that the quantity of polarised light is nothing at 0°, because the force which polarises it is there a minimum. At the maximum polarising light, Q is only 79·5, because the glass is incapable of reflecting more light at that angle, otherwise more would have been polarised. The value of Q, then, rises to its maximum at 78° 7′, and descends to its minimum at 90°; but the polarising force has not increased from 56° 45′ to 78° 7′, as the value of φ' shows. It is only the quantity of reflected light that has increased which occasions a greater quantity of light to disappear from the extraordinary image of the analysing rhomb.

"The case, however, is different with tne refracted light. The value of Q′ has one minimum at 0°, and another at 90°, while its maximum is at 78° 7′; while the force has its minimum at 0°, and its minimum at 90°, where its effect is a minimum only because there is no light to polarise. At the incidence of 78° 7′, where the quantities Q, Q′ reach their maxima, the reflected light is exactly one half of the transmitted light; $\sin.^2\varphi' = \cos.^2\varphi$ and $\tan.\varphi' = \cos.\varphi$.

"At 85° 50′ 40″, where the transmitted light is one half of the reflected light, the deviation $(i - i') = 45°$, and the quantity of polarised light is one third of the transmitted light, one sixth of the reflected light, and one ninth of the incident light. $\sin.^2\varphi' : \cos.^2\varphi$ = reflected light : transmitted light, and $\cot.\varphi = \sin.(i - i')$.

"At 45° we have $(i+i')+(i-i')=90°$ and $\varphi'=(i-i')$, $\tan.(i-i')=\frac{\cos.(i+i')}{\cos.(i-i')}$, and $\tan.(i-i')^2=\frac{(\sin.(i-i'))^2}{(\sin.(i+i'))^2}$.

"At 56° 45′, the polarising angle, the formula for reflected light becomes $R = \frac{1}{2}(\sin.^2(i-i'))^2$; but at this angle we have $i' = 90° - i$. Hence we obtain the following simple expression in terms of the angle of incidence, for the quantity of light reflected by all bodies at the polarising angle:

$$R = \tfrac{1}{2}(\cos.2\,i)^2."$$

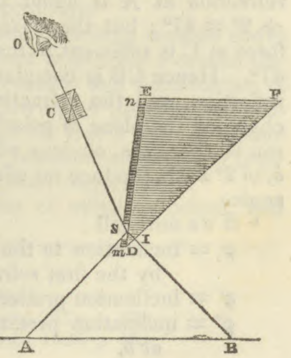
SECT. V.—*On the Action of Single Plates and Single Surfaces in polarising Light by Reflection and Refraction.*

In the article on the *polarisation* of light in this work, M. Arago has described an elegant experiment, from which he deduced the conclusion, that *the quantity of polarised light contained in the pencil transmitted by a transparent plate is exactly equal to the quantity of light polarised at right angles, which is found in the pencil reflected by the same plate.*

Now this law is true only at the maximum polarising angle, the two pencils being unequal at all other angles of incidence. The apparent equality observed by M. Arago seems to have arisen from other light being blended with the pencils. In order, therefore, to obtain the true law for single plates, we must determine it for a *single surface.*

In order to do this, Sir David Brewster employed a well-annealed prism of colourless glass, in place of a plate of glass, and he made the ray BI from a sheet of white paper BA enter the surface FD perpendicularly at I, while another ray AS was reflected to the eye from the surface ED of the prism. He then made the experiment with a doubly refracting prism C in the manner described by M. Arago, and obtained the law for *a single surface*, viz.

Fig. 141.



That the quantity of polarised light in the pencil re-

Polarisation.

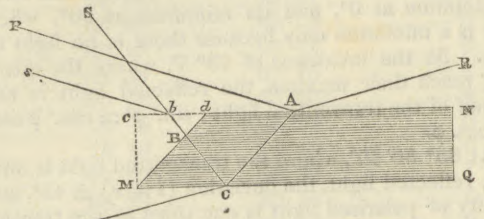
fracted by a transparent surface is exactly equal to the quantity in the pencil reflected by it.

That is, what was supposed to be true of plates is true only of surfaces.

The action of a single plate on light, involving the combined action of three refractions and two reflections, without following the light beyond one internal reflection, is sufficiently complex, and has been analysed in the following manner by Sir David Brewster.

He took a plate of glass of the form MN, fig. 142, having an oblique face Md cut upon one of its ends.

Fig. 142.



" A ray of light RA, polarised + 45° and — 45°, was made to fall upon it at A, at an angle of incidence of nearly 83°, so that the inclination of the planes of polarisation of the reflected ray AP was about $36\frac{1}{2}$°. Now the ray AC, after reflection in the direction CS, without any refraction at B, where it emerges perpendicularly to Md, would also have had the inclination of its planes of polarisation equal to $36\frac{1}{2}$° if there had been no intermediate refraction at A; but this refraction alone being capable of producing an inclination of 53°, or a rotation of 53° — 45° = 8°, and this rotation being in an opposite direction from that produced by the second reflection at C, the inclination of the planes of polarisation for the ray CS is nearly $44\frac{1}{2}$°, the reflection of C having brought back the ray AC almost exactly into the state of natural light.

" Without changing either the light or the angle, I cemented a prism Mcd on the face Md, so that cd was parallel to dN, and I found that the second refraction at b, equal to that at A, changed the inclination of the planes of polarisation to 53°; that is, the two refractive actions at A and b had overcome the action of reflection at C, and the pencil bs actually contained light polarised perpendicular to the plane of reflection.

" In order to put this result to another test, I took a plate Mc NQ (fig. 142) of the same glass, which separated the pencil bs reflected at the second surface, from the parallel pencil AP reflected from the first surface, and I found, that at an angle of 83°, the value of the inclination I or φ for the ray was about $37\frac{1}{2}$°, while the value of I for the ray bs was nearly 55°, an effect almost equal to the refractive action of a plate at 83° of incidence.

" When the pencil RA is incident on the first surface at the polarising angle or 56° 45′, the rotation produced by refraction at A is about 2°, or the inclination I = 45° + 2° = 47°; but the maximum action of the polarising force at C is sufficient to make I = 0° whether x is 45° or 47°. Hence CB is completely polarised in the plane of reflection, and the refractive action at b is incapable of changing the plane of polarisation when I = 0°; the reason is, therefore, obvious why the two rotations at A and b, of 2° each, produce no effect at the maximum polarising angle.

" If we now call

φ = inclination to the plane of reflection produced by the first refraction at A,

φ' = inclination produced by the reflection at C,

φ'' = inclination produced by the second refraction at b,

We shall have

$$\cot.\ \varphi = \cos.\ (i - i'), \text{ or } \tan.\ \varphi = \frac{1}{\cos.(i - i')},$$

$$\tan.\ \varphi' = \tan.\ x\ \frac{\cos.\ (i + i')}{\cos.\ (i - i')} = \frac{\cos.\ (i + i')}{(\cos.\ (i - i'))^2},$$

$$\cot.\ \varphi'' = \cot.\ x\ (\cos.\ (i - i')\ ) = \frac{(\cos.\ (i - i')\ )^3}{\cos.\ (i + i')}$$

" These formulæ are suited to common light, where x = 45°, but when x varies they become

$$\cot.\ \varphi = \cot.\ x\ (\cos.\ (i - i')\ ),$$

$$\tan.\ \varphi' = \tan.\ x\ \left(\frac{\cos.\ (i + i')}{(\cos.\ (i - i')\ )^2}\right),$$

$$\cot.\ \varphi'' = (\cot.\ x\ \left(\frac{(\cos.\ (i - i')\ )^3}{\cos.\ (i + i')}\right).$$

" Resuming the formula for common light, viz. $\cot.\ \varphi' = \dfrac{(\cos.\ (i - i')\ )^3}{\cos.\ (i + i')}$, it is obvious that when $(\cos.\ (i - i')\ )^3 = \cos.\ (i + i')$, $\cot.\ \varphi'' = 1$, and $\varphi'' = 45°$; that is, the light is restored to common light.

" In glass where m = 1·525 this effect takes place at 78° 7′, a little below 78° in diamond, and a little above 80° in water.

" At an angle below this φ becomes less than 45°, and the pencil contains light polarised in the plane of reflection; while at all greater angles φ is above 45°, and the pencil contains light polarised perpendicular to the plane of reflection. Hence we obtain the following curious law:

" ' *A pencil of light reflected from the second surfaces of transparent plates, and reaching the eye after two refractions and an intermediate reflection, contains, at all angles of incidence, from* 0° *to the maximum polarising angle, a portion of light polarised in the plane of reflection. Above the polarising angle the part of the pencil polarised in the plane of reflection diminishes till* $\cos.\ (i + i') = (\cos.\ i - i')\ )^3$, *when it disappears, and the whole pencil has the character of common light. Above this last angle the pencil contains a quantity of light polarised perpendicular to the plane of reflection, which increases to a maximum and then diminishes to zero at* 90°.'

" Let us now examine the state of the pencil CS′ after only one refraction and one reflection. Resuming the formula $\tan.\ \varphi' = \dfrac{\cos.\ (i + i')}{(\cos.\ (i - i')\ )^2}$, it is evident that when $(\cos.\ (i - i')\ )^2 = \cos.\ (i + i')$, $\varphi' = 45°$, and the light restored to common light. This takes place in glass at an angle of 82° 44′. At all angles beneath this the pencil contains light polarised in the plane of reflection; but at all angles above it, the pencil contains light polarised perpendicular to the plane of reflection, the quantity increasing from 82° 44′ to its maximum, and returning to its minimum at 90°.

" Let us now apply the results of the preceding analysis to M. Arago's experiment. Suppose the angle of incidence to be 78° 7′, and let the light polarised by reflection at A (fig. 142) be = m, and that polarised by one reflection also = m. Then, since the pencil bs is common light, the polarised light in the whole reflected pencil AP, bs, is = m, whereas the light polarised by the two refractions is = $2m$; so that the experiment makes two quantities appear equal when the one is double that of the other. If the angle exceeds 78° 7′, the oppositely polarised light in the pencil bs will neutralise a portion of the polarised light in the pencil AP, and the ratio of the oppositely polarised rays which seem to be compensated in the experiment may be that of $3m$ or even $4m$ to 1.

" We may now obtain formulæ for computing the exact quantities of polarised light at any angle of incidence, either in the pencil CBS or bs.

Polarisation.

"The primitive ray RA being common light, AC will not be in that state, but will have its planes of polarisation turned round a quantity x by the refraction at A; so that $\cot. x = \cos. (i - i')$. Hence we must adopt for the measure of the light reflected at C the formula of Fresnel for polarised light whose plane of incidence forms an angle x with the plane of reflection. The intensity of AC being known from the formula for common light, we shall call it unity, then the intensity I of the two pencils polarised $-x$ and $+x$ to the plane of reflection will be

$$I = \frac{\sin.^2 (i - i')}{\sin.^2 (i + i')} \cos.^2 x + \frac{\tan.^2 (i - i')}{\tan.^2 (i + i')} \sin.^2 x, \text{ and}$$

$$Q = I \left(1 - 2 \frac{\left(\frac{\cos. (i + i')}{(\cos. (i - i'))^2} \right)^2}{+ 1 \left(\frac{\cos. (i + i')}{(\cos. (i - i'))^2} \right)} \right)$$

"In like manner, if the intensity of CB $= 1$, we have

$$\tan. x = \frac{\cos. (i + i')}{(\cos. (i - i'))^2},$$

and the intensity I of the transmitted pencil bs

$$I = 1 - \frac{\sin.^2 (i - i')}{\sin.^2 (i + i')} \cos.^2 x + \frac{\tan.^2 (i - i')}{\tan.^2 (i + i')} \sin.^2 x \text{ and}$$

$$Q = \left(I\, 1 - 2 \frac{\left(\frac{(\cos. (i - i'))^3}{\cos. (i + i')} \right)^2}{1 + \left(\frac{(\cos. (i - i'))^3}{\cos. (i + i')} \right)^2} \right)$$

"The following table, computed from the formulæ in the preceding page, shows the state of the planes of polarisation of the three rays AC, CS, and bs.

Angle of Incidence on the First Surface.	Angle of Refraction at First Surface, and Angle of Incidence on Second Surface.	Inclination of Plane of Polarisation of AC, fig. 142.	Inclination of Plane of Polarisation of CS, fig. 142.	Inclination of Plane of Polarisation of bs, fig. 142.

Sect. VI.—*On the Polarisation of Light by Absorption and Dispersion.*

In the preceding section we have considered common light as consisting of two pencils of polarised light, having their planes of polarisation at right angles to each other. The very same results would take place if we considered a beam of light as consisting of two sets of polarised rays, all those of one set having their planes of polarisation in every possible direction, and of another set having their planes of polarisation at right angles to those of the former.[1] In this view of the subject, common light is polarised when it issues from the luminous body, and when we polarise it or decompose it by double refraction, or polarise it completely by reflection or refraction, we merely separate the one half of it polarised + from the half polarised —. This effect is analogous to the decomposition of white light into its colours. All the colours exist in the sun's light, and they are merely separated by prismatic refraction, or by interference, or by absorption.

Now common light may also be decomposed by dispersion and absorption; that is, if we can contrive any method of dispersing or absorbing *one of the two polarised pencils* of common light, we shall exhibit the other pencil in its state of natural polarisation.

Crystals in which this effect is produced are called singly polarising or singly refracting crystals. They were first observed and described by Sir David Brewster in the year 1812.[2] The first mineral in which he discovered this property was the agate, in which one of the pencils is dispersed into a nebulous mass of light, sometimes of the form of a crescent, so that the bright image was all polarised in one plane, like one of the pencils of Iceland spar. The mass of nebulous light, too, was always polarised in a plane perpendicular to that of the bright image.

The same author discovered a similar property in certain specimens of the carbonate of barytes, which exhibited several interesting phenomena,[3] in thick crystals of mica,[4] and in mother of pearl,[5] and very curiously in oil of mace,[6] and other substances. The same property he found in various artificial crystals, but particularly in nitre.

Another very beautiful example of polarised nebulous images was observed by the same author in an artificial kind of nacre already referred to, in which there are three nebulous polarised images, with a bright image enclosed in the middle one of the three nebulous images.[7]

A similar property was discovered in 1815 in the *tourmaline*, nearly about the same time, by M. Biot and M. Seebeck, the priority belonging to the former. This crystal has double refraction, like all other crystals of the same class; but when it is cut by planes passing through the axis of the crystal, and has a certain thickness (about the twenty-fifth of an inch, but which varies in different specimens), it transmits only one of the pencils formed by double refraction. The pencil polarised in the plane of the principal section is absorbed, or somehow or other lost, while the one depolarised at right angles to that section is transmitted. If we take two such plates of tourmaline, and place them with their axes parallel, the unabsorbed pencil will be freely transmitted through both; but if we begin to turn one of them round, the light will become fainter and fainter, and the luminous object will vanish entirely when the axes are at right angles to each other. By continuing to turn, the image again appears, reaches its maximum when the axes are parallel, and then vanishes when the axes are at right angles. The same phenomenon is exhibited by the *agate* in reference to its distinct image.

In all the singly refracting and polarising crystals above enumerated, the effects described arise from a certain degree of imperfection in the structure and combination of the elementary crystals, by which one of the polarised pencils is reflected or absorbed; but Sir David Brewster found that the same property may be communicated to any crystal, *merely by altering its superficial conformation.*

If we take a hexahedral prism of *nitrate of potash,* and

Polarisation.

observe a luminous object through two of its inclined surfaces that have a good natural or artificial polish, we shall perceive two distinct and perfectly formed images. If we now roughen these two surfaces, and cement upon each of them a plate of glass by means of *balsam of capivi*, the character of the two images will be greatly changed. The image that has suffered the *greatest* refraction will be as *distinct* as before, but the other image will be either of a *faint reddish colour*, or wholly invisible, according to the degree of roughness induced upon the refracting surfaces. When *oil of cassia* is used instead of the balsam, the *least refracted image*, if it was visible before, will now be *completely extinguished.*

By substituting pure *alcohol*, or the *white of an egg*, instead of the balsam, the *least refracted image* will become *distinct*, and the *most refracted image* will be either a mass of *nebulous light*, or almost invisible.

In order to explain these phenomena, we must recollect that the index of refraction for the *ordinary* image of *nitre* is 1·511, and that of the *extraordinary* image 1·328. When the rough surface of the nitre is covered with balsam of capivi, which has nearly the same index of refraction as the ordinary image, the same effect is produced as if the rough surface had been polished for the ordinary rays. All the little pits or depressions in the rough surface being filled up with balsam, the ordinary rays suffer little or no refraction in penetrating the crystal, and therefore the image which they form will be as clear and distinct as in the first experiment. But since the index of refraction for the extraordinary image is much less than that of the balsam, the rays of which it is composed will not enter the crystal undisturbed, but will be scattered in the same manner as if its surface was rough, and had a refractive power corresponding to the difference between the index of refraction for the extraordinary ray, and the index of refraction for the balsam. When *water* or *alcohol* is substituted in room of the *balsam*, the effects now described are interchanged, the roughness being removed for the extraordinary rays by the application of a fluid of the same refractive density, while the rays that form the ordinary image are dispersed by the refractions which still exist at the rough surface of the crystal.

These effects will be better understood by supposing the crystal to consist of an extraordinary and an ordinary medium, arranged in alternate strata, or as water exists in wet hydrophanous opal. When the superficial polish of both these media is removed, the application of the *balsam* restores, as it were, the polish of the ordinary medium, without restoring that of the extraordinary medium; while the application of the *alcohol* restores the polish of the extraordinary medium without restoring that of the ordinary medium.

These results were repeatedly obtained with *calcareous spar, arragonite, nitre, carbonate of potash*, and other crystals;[1] and we have now before us a singly-polarising prism of *Iceland spar*, made nearly twenty years ago, which answers all the common purposes of a plate of tourmaline or a parcel of glass plates.

Sect. VII.—*On the Depolarisation of Light, and the Colours of thin Crystallized Plates in Polarised Light.*

The phenomena which we are about to describe are among the most splendid in optics. They were discovered by independent observation by M. Arago and Sir David Brewster; the priority of discovery belonging to M. Arago. The very same colours, indeed, as we shall presently see, had been observed by Huygens, Robison, Malus, and others, in Iceland spar; but they were not aware of their nature and origin.

There are *four* methods of exhibiting these colours, which may be used at pleasure, and each of which has its advantages.

1. If we take a plate of *agate* or *tourmaline*, or any other of the artificial singly-polarising crystals already described, and having cut it into two parts, each of which is at least equal to the diameter of the pupil of the eye, though this is not absolutely requisite, fix each of them above an aperture in a piece of card or brass, so that no light passes at their edges. Let them be now placed at the distance of an inch or more, the one near the eye being capable of turning round the axis of vision; and let this last be turned into such a position that the light of the sky, or that of a flame enlarged by a lens placed near it, is no longer able to penetrate the second singly-refracting plate.

If we now introduce between the two plates of tourmaline, for example, a plate, either thick or thin, of any doubly-refracting substance, we shall observe very curious effects. If the plate is *thick*, such as one of sulphate of lime, the 30th of an inch and upwards, we shall find that the insertion of the plate has *revived*, as it were, the light which refused to pass through the second plate, and this light will be white. If we turn the sulphate of lime round, we shall find *four positions* 90° from each other, in which the revived light is a maximum; and other four bisecting these, and also 90° from each other, in which the light entirely vanishes, as before the sulphate of lime had been introduced.

This property of reviving the light has been called the *depolarisation of light*, because the sulphate of lime deprives the rays polarised by the first plate, of that kind of polarisation which prevented them from penetrating the second plate.

But if the plate is thin, between the fiftieth and the seventy-fifth of an inch, we shall have precisely the same phenomena, with this difference only, that the restored light is brilliantly coloured. The colours vary in intensity, like the white light, disappearing in the positions 0°, 90°, 180°, and 270°, and reaching their maximum at 45°, 135°, 225°, and 315°. If we now turn the plate of tourmaline next the eye round 90°, so that the axis of the two plates are parallel, and the pencil polarised by the first freely transmitted by the second, and if we then introduce the same plate of sulphate of lime as before, we shall now find that in the *four* positions of it, viz. 0°, 90°, 180°, and 270°, where no light or colours were formerly, nothing but white light is visible; but that at the positions 45°, 135°, 225°, and 315°, where the maxima of light and colour took place, we have the maxima of a colour *complementary* to that formerly seen, the intensity of this colour gradually increasing from nothing at 0°, reaching its maximum at 45°, again diminishing to 90°, and so on with the other quadrants. These colours are called the *colours of crystallized plates, or the colours of polarised light.*

In the preceding experiment with plates of tourmaline, we see only one of the two complementary colours, while the position of the tourmaline remains the same. The disadvantage of using the tourmalines is, that, from their brown colour, the brilliancy of the polarised colours is greatly injured; and the tourmalines therefore cannot be employed, either when we wish to have the most brilliant representations of the phenomena, or when it is necessary to study the exact tints which are developed.

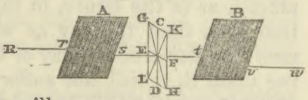
But if we use the plates of *agate* or of roughened Ice-

[1] Phil. Trans. 1819, p. 146

land spar in the same manner, we shall not only have identically the same phenomena of colour in the bright and distinct image formed by the agate with a purer light; but we shall have the additional phenomenon of this bright coloured image placed in the middle of a *nebula* or haze of the *complementary* colour, so that we here see both the colours at the same time, and without any of the superadded brown colour imparted by the tourmaline. If the colour of the distinct image is *green*, it will be encircled by a haze of *red* light; if it is *blue*, with a haze of *orange* light; and so on.[1]

2. The *second* method consists in placing the film of *sulphate of lime* GKHL between two bundles of glass plates A and B, which polarise the light by *refraction*, as shown in the annexed figure. A ray R*r* emerges from A, polarised as at *st*, and will freely penetrate the second bundle B, and emerge, as shown at *vw*, when the planes of refraction of A and B are parallel, as in the figure; but not a ray of *st* will emerge at *v* when the planes of refraction are perpendicular to each other. When we interpose, therefore, the sulphate of lime GKHL, it will exhibit *identically* the same phenomena as between the tourmaline plates, the bundle A corresponding to the fixed plate, and B to the moveable one, and the planes of refraction corresponding to the axes of the tourmaline. If we suppose the bundles A and B to be placed with their planes of refraction perpendicular to each other, then the position of the plate of sulphate of lime, in which no colour appears, is, when its axis of double refraction CD is its principal axis (viz. the line bisecting the resultant axis) if it is biaxal, *parallel* or *perpendicular* to the planes of refraction. When CD, therefore, or EF (perpendicular to it), is in the plane of refraction of A, or *the plane of primitive polarisation*, as it is called, not a ray of coloured light reaches the eye at *v*, and hence these have been called the *neutral axes* of the plate of sulphate of lime, because they produce no change upon the ray *st*. On the other hand, when the lines GH, KL, perpendicular to each other, and inclined forty-five degrees to the *neutral axes*, are in the plane of primitive polarisation, the coloured light depolarised is a maximum, and hence they have been called the *depolarising axes* of the plate GKHL, names which will be found very convenient in the description of phenomena.

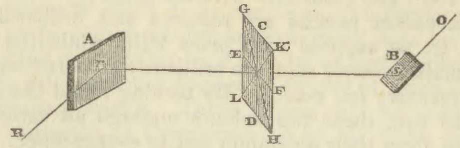
Fig. 143.



It is an interesting fact, which was discovered by Sir David Brewster, that nature actually presents us, in the case of certain crystals of *nitre*, with the whole of the apparatus in the space of half an inch. One part of the crystal has its laminæ inclined like the bundle A, while another part has them lying in a rectangular direction like B; so that such a crystal, by merely looking through it when the opposite faces are either polished by art or by a cement, exhibits its own coloured rings. Sir John Herschel subsequently observed the same fact in carbonate of potash, and proposes to call such crystals *idiocyclophanous*, or *those which show their own rings*.

3. The *third* method is shown in the annexed figure, where A is a plate of black glass (or a bundle of 8 or 12 plates of thin transparent glass, for the purpose of increasing the light), which polarises in a horizontal plane a ray R*r*, incident at an angle of 56°, reflecting it polarised in the direction *rs*, where it is received upon a second plate of black glass B at the same angle of 56°, so

Fig. 144.

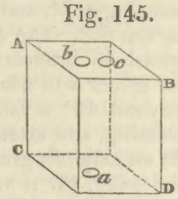


as to reflect it to the eye at O. If the plane of reflection from B is vertical, so as to be perpendicular to that from A, not a ray of the pencil R*r* will be reflected, but the eye at O will perceive a large black spot on the part of the sky or other luminous surface from which the ray R*r* proceeds.[2] The plate or plates at A are called the *polarising plates*, and that at B the *analysing plate*.

The plate of sulphate of lime is then placed at GKHL, anywhere between the plates, and it will exhibit the very same phenomena as between the tourmalines and the bundles of plates, though with more brilliancy and distinctness, as there is no brown colour to disturb the tints, and no haziness, as happens with the second bundle B of plates of glass. In this method the planes of reflection perform the same part as the axis of tourmaline and the planes of refraction in the other cases.

4. The *last* method which we shall mention, is to employ rhombs of Iceland spar, both for polarising and analysing the light. If the Iceland spar is converted into two of Nicol's prisms, then each prism performs exactly the same part as the tourmaline and the reflectors, exhibiting only one of the complementary colours. This ingenious contrivance, which derives its name from its inventor, William Nicol, Esq. of Edinburgh, consists of two pieces of calcareous spar cemented together so as to transmit only one of the polarised pencils; but the difficulty and expense of constructing it well, and the risk of a change in the state of the cement which unites the two parts, render it desirable to have a simple, a cheap, and a durable substitute for it. The polariser and analyser used by Sir David Brewster in many of his experiments in elliptical polarisation, and in the action of crystallized surfaces, was a *single* rhomb of calcareous spar, having thin plates of colourless glass cemented to its natural surfaces by Canada balsam, which, while it removes any imperfection of surface, protects the surfaces from any accidental injury, or from the deterioration of the polish arising from frequently cleaning them. This rhomb, shown at ABCD, may be of any thickness suited to the diameter of the pencil of light which we wish to have. By a rhomb one inch thick we can obtain a pencil of light 0·115 of an inch in diameter; by placing an aperture of that diameter at *a* on the lower side CD, we obtain two pencils *b*, *c*, polarised in opposite planes, and just touching each other. If we wish to use only one pencil, we can conceal *b* or *c* with a wafer, and use the other; but for the purpose of our present experiment they may both be left clear. If we now construct an exactly similar, or a larger rhomb, without any aperture upon it, and place the two as we did the tourmaline plates, or in any of the positions shown in fig. 130, we shall see only *two* images, the other two being evanescent. Let the plate of sulphate of lime be now interposed as formerly, and we shall find, that when its principal axis CD forms angles of 0°, 90°, 180°, and 270° with the plane of the principal section of the rhombs, no

Fig. 145.



Fourth method.

[1] We would recommend it to Mr Watkins to prepare this apparatus with the same ingenuity with which he has done the other apparatus for exhibiting the other phenomena of polarised light.

[2] The appearance of this black spot shows that the two reflectors are properly adjusted, so as to save all the trouble of attending to the angles at which the rays are incident on the two reflectors A and B.

Polarisation.

light is depolarised; but that when the axis forms angles of 45°, 135°, 225°, and 315° with the principal section, the *two* evanescent pencils are restored and brilliantly coloured, let us suppose with *green* light, while the other two pencils formerly seen are brilliantly coloured with the complementary *red* colour. By turning round the rhomb next the eye, these two colours undergo all varieties of intensity, from their maximum tint to evanescence.

If we now enlarge the aperture *a*, fig. 145, in the first rhomb, so that the two images *b*, *c*, in place of being in contact, overlap each other, we shall have the parts that do not overlap exhibiting the two complementary colours as before, while the parts that do overlap form *perfectly white light;* thus proving that the two colours are exactly complementary to each other. Any of the images *b*, *c* may be enlarged, if necessary, by a convex lens placed before them, or by other means.

In order to obtain a large pencil of polarised light *b* or *c*, we must make the rhomb very thick; but there is another way in which we may obtain the same effect in thin rhombs. There are particular specimens of the spar which are interrupted with veins, and which will be described in a separate section. If we obtain one of these in which the vein has a certain thickness, it will produce polarised images on each side of *b* and *c*, and these images will be perfectly *white*. We may therefore use a much larger aperture *a*, and obtain a very effective apparatus. This, however, will be better understood afterwards.

When the *veins* above mentioned are *thin*, these lateral images are beautifully coloured, the colours being portions of the coloured rings produced by the thin vein, the prism in front of the vein polarising the light, and the prism behind it analysing it.

These different methods of exhibiting the colours of crystalline plates may be varied, if we use a plate of glass as the polariser, and a tourmaline for the analyser; or, in short, we may use one half of each apparatus with one half of the other. When we wish to have a large surface of polarised light, the best and readiest is a large surface covered with black varnish.

In the preceding observations, with the *four* different kinds of apparatus, we have supposed the polariser and analyser to be fixed, either with their similar planes parallel or perpendicular to each other, and the plate of sulphate of lime to be moved round its axis. Let us suppose, however, that the sulphate of lime is *fixed* in the position where its colour, *bright red*, for example, is a maximum; that is, where any of the depolarising axes GH or KL, fig. 144, is parallel or perpendicular to the plane R*rs* of primitive polarisation. In this position of GH, let the analysing plate B be made to revolve round the ray *rs*, its motion commencing at 0°, and always keeping the same inclination to *rs*, viz. 56°. The *bright red* visible at 0° will gradually diminish in intensity as B moves from 0° to 45°, when the *red* colour will wholly vanish, and the black spot be seen. Beyond 45° a faint *green* tint will appear, gradually increasing, and attaining its maximum of brightness at 90°. At an azimuth greater than 90°, the green becomes paler and paler, till it vanishes wholly at 135°. Here the *red* again begins, and reaches its maximum brightness at 180°. Similar changes take place while the plate B moves from 180° to its original position at 360° or 0°. Hence it appears, that when the sulphate of lime alone revolves, only one of the complementary colours is visible, whereas, when the plate B only revolves, both the complementary colours are visible during each half of its revolution.

When these experiments are repeated with plates of sulphate of lime, or any other mineral having different thicknesses, different colours will be produced, varying with the thickness; and in every case the two colours which are produced, either when we use the two polarising rhombs, or cause the reflector B to revolve, are always *complementary* to each other, or together make white light.

If we remove the plate B, and look through the sulphate of lime, we shall find that the light which it transmits is always white, whatever be the position of the sulphate of lime, whatever be the inclination which the ray R*r* forms with the polariser A, and whatever be the condition of the polariser itself. The decomposition of the white light, therefore, or its separation into two complementary colours, must be effected by reflection from the plate B. Now sulphate of lime is a doubly refracting crystal, giving two oppositely polarised images, lying above one another, and one of its neutral axes CD is the section of a plane passing through its principal axis of double refraction, while EF is the section of a plane perpendicular to that section. Let any of these planes, suppose EF, be placed, as in the figure, in the plane of primitive polarisation R*rs*, then the ray *rs* will not be doubled, but will pass into the ordinary ray of the sulphate of lime, and falling upon B, it will not suffer reflection. The very same will happen if CD is brought into the plane of primitive polarisation, so that in these two positions none of the light transmitted through the sulphate of lime will suffer reflection at B, and reach the eye at O. In all other positions, however, of the sulphate of lime, it forms *two* images or pencils of different intensities; and when either of the depolarising axes GH or KL is in the plane of primitive polarisation R*rs*, these two images or pencils will be of equal intensity, and polarised in opposite planes. Now, one of *these* images is *red*, and the other *green*, a fact which will be afterwards explained; and as the *red* is polarised in the plane of primitive polarisation, it will not suffer reflection from B; while the *green*, being polarised in the plane of reflection from B, will be reflected to the eye at O, and is therefore seen alone. From the same cause, when B is turned round 90°, the *green* will not suffer reflection from it; while the red will suffer reflection, and be seen by the eye at O. The plate B has therefore analysed the compound beam of *red* and *green* light by reflecting one and transmitting the other colour.

Now, if the sulphate of lime had been thicker than the fiftieth of an inch, the two pencils would have been both white; and when the plate was moved round, we should have had a white pencil reflected from B, and undergoing the very same changes that the coloured one did. Hence we see the cause of the *depolarisation of light*, both when the depolarising plate is thick and thin.

In the preceding experiments, the sulphate of lime has been supposed to be so thin as to give a *red* and a *green* tint; but if the plate is only 0·00046 of an English inch thick, it will depolarise no light at all, either coloured or uncoloured, and the black spot will be seen in every position of the sulphate of lime. If the thickness of the plate is 0·00124 of an inch, the light depolarised will be the *white*, the first order of Newton's scale, whose complementary colour is a deep *violet;* and if the plate is 0·01818 of an inch, or upwards, it will also polarise white light, composed of all the colours of the spectrum. When the plates of the mineral have an intermediate thickness between 0·00124 and 0·01818, they will give, at successive thicknesses, all the intermediate colours in Newton's table, between the white of the first order, and the white compounded of all the colours. The colours from the plate B will be those in col. 2 of Newton's table, while the colours seen in turning round the plate B will be the complementary ones in col. 3 of the same table, the one corresponding to the *reflected* and the other to the *transmitted* tints of thin plates.

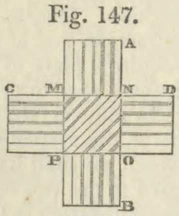
By a variety of accurate experiments, M. Biot pointed out the connection between the colours of polarised light and of thin plates; and in the case of sulphate of lime, the films of which he measured with an ingenious instrument invented by M. Cauchoix, called the spherometer, he has proved that the thicknesses which produce the different colours in Newton's table are proportional to the value of the tints in the last column of Newton's table for glass; this substance having nearly the same refractive power as sulphate of lime. If we wish, for example, to know the thickness of sulphate of lime which will give the *red* of the first order of colours, the number in the last column opposite red is $5\frac{4}{5}$ths; then, since the *white* of the *first* order is produced by a plate 0·00124 of an inch thick, the number opposite which is $3\frac{2}{5}$ths, we say, as $3\frac{2}{5}$ths is to $5\frac{4}{5}$ths, so is 0·00124 to 0·00211, which is the thickness at which sulphate of lime depolarises the *red* of the first order. By reversing this rule we can determine the colour which will be depolarised at any given thickness. This law of the colours is by no means general, and we shall presently see that the colours of polarised light bear frequently no relation whatever to those of thin plates.

The above phenomena may be beautifully exhibited to the eye by combining pieces of sulphate of lime into a painted Gothic window, so that when the window is exposed to common or to polarised light it appears perfectly colourless, but when seen by reflection, it will exhibit all the splendid colours of the separate films. Though this experiment is well suited for exhibition, yet the following one, which was also made by Sir David Brewster, is more instructive. Selecting an uniform plate of sulphate of lime, about the twenty-fifth of an inch thick, he ground down,[1] with the powder of schistus, one of its faces, so as to make it a sort of wedge, in which the thickness varies from the twenty-fifth of an inch down to the thinnest edge that could be made. The plate was then placed in water, which acted upon it slowly, making its edge thinner, and giving a slight polish to its surface. When this film is placed at GH, in fig. 144, its figure will be seen covered with coloured fringes, as in fig. 146, parallel to its edges. At its thinnest edge the colours of the first order will commence from *black*, and gradually increasing, as in Newton's table, till, at the thick edge AD, we have the sixth or seventh, or higher orders of colours. Here we see at once how all the different tints and different orders are connected with the different thicknesses of the plate.

Fig. 146.

If we now cut this plate into two equal parts AB, CD, and cross them as in the figure, a *new set of fringes* will appear, parallel to a line joining the points where the two thinnest and the two thickest edges intersect, that is, parallel to NP, one of the diagonals of the intersectional square MNOP. The line NP will be black, and from NP to M and N the fringes will be exactly the same as those from the thin to the thick edge of the plate.

Fig. 147.



If the plates *ab, cd* have their axes at right angles to each other, there will be only one set of fringes, beginning at the angle where the two tints are minimum.

If we grind one side of the plate spherical, so that the thickness shall vary like the plate of air between a convex and a plane surface, then, by combining a plate of this kind with a prismatic plate, or by combining two similar plates, and by varying their maximum thicknesses, their breadths, &c. we shall produce, by their parallel or rectangular combination, intersectional fringes of figures of great variety and extreme beauty. These figures will be analogous, *mutatis mutandis*, to those observed by Mr Knox, and the far more splendid exhibitions produced by crossing plates of glass in the manner described in a subsequent chapter.

Polarisation.

If we grind *concave* surfaces on one of the faces of the crystalline plate, we shall have circular rings, equidistant if the concavity is conical, but resembling those of thin plates if it is spherical. These plates may also be combined with those which give circular and rectilineal fringes, and very fine effects produced by the combination.[2] Still more remarkable effects may be produced by turning beautiful patterns upon the sulphate of zinc, or etching them either by the action of pure *water*, or water slightly acidified. Lines of equal depths will be all equally coloured, and the slightest differences in depth, which can be easily regulated by a fine turning-lathe, will produce a great variety of different colours. Coloured figures and landscapes may be executed by scraping away the surface to the thickness necessary to produce the requisite tints. A cipher, too, might be executed upon a mineral; and if we cover the surface upon which it is formed with a fluid of the same refractive power, it will be absolutely illegible by common light, but may be distinctly deciphered when placed between the polarising and analysing plates.

A sheet of ice irregularly frozen, and held in the position just mentioned, exhibits the colours of crystallized plates in a splendid manner; but if in a severe winter, when ice can be handled without melting, we take an uniform plate, and dissolve a pattern upon it by heat, which may be applied in many ways, so as to affect only the parts to be made thinner, we shall observe a phenomenon than which nothing can be more splendid.

Sect. VIII.—*On the System of Rings produced by Uniaxal Crystals.*

In the preceding experiments the crystallized plate is held at such a distance from the polarising plate that its surface could be distinctly seen by the eye; and it was from observations made in this manner that M. Biot deduced his empirical formulæ for expressing the variation of the tint, as depending on the thickness of the crystallized plate, and on the square of the sine of the inclination of the refracted ray to the axis of the crystal.

Rings in uniaxal crystals.

From this mode of observation M. Biot concluded, that *arragonite, topaz, sulphate of lime, felspar, sulphate of barytes, and sulphate of strontian*, were all crystals with one axis of polarisation and double refraction. In 1813, however, Sir David Brewster was led to an entirely different mode of observation. He brought the crystal or plate as close to his eye as possible, and by using a large polarising plate, such as a black japanned tray, he was able to see, *at the same instant*, the colours produced at various angles of inclination, in place of determining the loci of these colours, as was done in the old way, by a great number of insulated observations.

When, for example, he looked through the *ruby*, the *emerald, topaz, ice, nitre*, and other bodies, he observed the most beautiful system of rings when the polarised light

[1] The plate may be cemented by one of its faces to a piece of plate-glass, which will protect it from breaking, and after it is finished and bisected, each half should be enclosed between two glass plates.

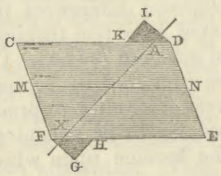
[2] We would recommend to the practical optician the construction of such plates as a matter of trade.

Polarisation.

passed along the axis of double refraction of these bodies. The rings in crystals with one axis are essentially different from those with two axes.

The *uniaxal system of rings* is represented in Plate CCCLXXXIII. fig. 29, 30. I discovered them in all the doubly refracting crystals with one axis, already mentioned, excepting in Iceland spar, in which they were first observed by Dr Wollaston, and independently by M. Biot and Dr Seebeck. This system of rings is seen along the axis of double refraction; and it has been customary to cut faces upon the obtuse angles of the rhomb of calcareous spar perpendicular to the axis, in order to see them. Sir David Brewster, however, employed the simple method shown in the annexed figure, which does not require the aid of the lapidary. Let CDEF be the principal section of a rhomb of Iceland spar; cement upon CD and EF two small prisms DLK, FGH, having the angles LDK, GFH about 45°. each; and let this rhomb be placed between the polarising and analysing plates, so that the polarised ray *rs* passes perpendicularly through the faces LD, FG. The rhomb must be held as close as possible to the reflector B, which need not be larger than the pupil of the eye. When the black spot is seen on the reflector B, in the apparatus as adjusted, then, when the rhomb is interposed, the observer, with his eye close to the plate B, and looking, as it were, through the reflected image of the rhomb, will see the beautiful system of rings shown in fig. 29, Plate CCCLXXXIII., intersected by a black rectangular cross AB, CD, the arms of which are parallel and perpendicular to the plane of primitive polarisation. The colours of the rings, of which seven or eight may be readily seen, are almost exactly the same as those of the reflected rings in thin plates, as seen in Newton's table or scale of colours.

Fig. 148.



If we turn the rhomb round its axis, the rings will suffer no change, the four arms of the black cross revolving round the circumference of the rings, or rather these four arms remain fixed, and the rings revolve with the rhomb.

If the rhomb is now fixed so that the rings are distinctly visible, and if we cause the plate to revolve from zero or 0°, then the rings will change into the form shown in fig. 30, Plate CCCLXXXIII., in which the black cross is broken up; and at 45° the rings will appear as in fig. 31, which is the *complementary system*, with a white centre exactly similar to the system seen by transmission in thin plates. These two systems of rings superposed or placed one above the other, would produce uniform white light, without any trace of rings. By continuing to turn B, the *primary system*, fig. 29, will re-appear at 90°, 180°, and 270°; and the *secondary system*, fig. 31, at 45°, 135°, 225°, and 315°; while the *intermediate system*, fig. 30, will be seen at intermediate azimuths.

It is very interesting to trace the passage of the *primary* into the *secondary* system. When B begins to turn, the arms of the black cross widen and become less black, and within them we can see segments of the *complementary* rings, whose dark intervals correspond to the bright ones of the primary rings, and *vice versa*. As B advances, the rings of the primary set grow less, and more dilute, while the others grow larger and brighter, till, at 45°, the *secondary* set is complete. When the light previous to polarisation has passed through ground glass, the diluted primary rings appear of a gray-white colour, and as if they were nearer the eye than the rest.

If, in place of the plate B, we use a polarising rhomb or an achromatised prism of Iceland spar, and look through it along the axis of the other rhomb, then, when the plane of its principal section is parallel or perpendicular to the plane of primitive polarisation, we shall see in one of its two images the *primary* system of rings, and in another the *secondary* system; and in intermediate positions we shall see the intermediate system, the one constantly passing into the other.

When all these experiments are repeated in homogeneous light, the system of rings will be *smallest* in *violet*, and *largest* in *red light*, and of intermediate sizes in intermediate colours.

If we divide the rhomb of spar, fig. 148, into two parts by the line MN, and examine the rings through each separately, we shall find that the rings produced by each part are *larger* than those produced by the whole, the thinnest piece producing the largest rings. Hence two rhombs united will give a system of rings corresponding to those produced by one rhomb of the same magnitude.

The systems, if formed by *zircon*, *ice*, and positive doubly-refracting crystals, are exactly the same as the preceding. But if we unite a positive system with an equal negative system, they will destroy each other; and if the two systems are unequal, we shall have a system equal to the difference of their effects. These experiments of combining systems of positive and negative rings, though rather troublesome, are extremely interesting. When such systems are combined, and the space between the crystals that form them left open, a series of splendid changes are induced upon the resulting system, by placing one or more crystallized films in one or more azimuths between them; but we shall have occasion to return to this subject in the section on the multiplication of images by Iceland spar.

In examining the phenomena of the primary rings, it is obvious that there is no polarisation, as there is no double refraction along the axis of the crystal. The tints polarised increase with the double refraction, that is, with the inclination of the polarised ray to the axis of double refraction; and their numerical value, as given in Newton's scale, increases with the square of the sine of that inclination. At any given inclination to the axis the tint increases with the thickness through which the polarised ray passes, so that when we have determined the tint at any given inclination and thickness, it is easy to find it for another inclination and thickness.

In crystals with one axis of double refraction, the lines of equal double refraction are circles when the thickness is equal, as in a sphere; in like manner, the lines of *equal tint*, or the *isochromatic lines*, are circles, the tints being a maximum in the equator, where the inclination to the axis is 90°. In crystals with great double refraction the same tint at the same inclination to the axis is produced at a much less thickness than in crystals with feeble double refraction. Quartz, for example, has a very feeble double refraction, and at the same inclination to the axis it would require a plate of quartz 115 times as thick as a plate of Iceland spar to produce the same tint in Newton's scale.

In some crystals with one axis, such as quartz, amethyst, beryl, the system of rings is disturbed by secondary causes, which we shall have occasion to refer to more fully in regard to the two first crystals. In other crystals imperfect crystallization is the general cause of these irregularities.

In Iceland spar, zircon, ice, tourmaline, and various other minerals, the tints of the rings are very nearly those of Newton's scale; but there are other crystals, such as apophyllite, in which Sir David Brewster and Sir John Herschel discovered remarkable deviations, which will be described in a subsequent section.

The intensity of the polarising force, or the value of the tint polarised at a given thickness, has been calculated by different persons for different crystals. The following have been given by Sir John Herschel for uniaxal crystals.

	Numerical Value of the highest Tint.	Thicknesses that produce the same Tint.
Iceland spar	35801	0·000028
Hydrate of strontia	1246	0·000802
Tourmaline	851	0·001175
Hyposulphate of lime	470	0·002129
Quartz	312	0·003024
Apophyllite, first variety	109	0·009150
Camphor	101	0·009856
Vesuvian	41	0·024170
Apophyllite, second variety	33	0·030374
third variety	3	0·366620

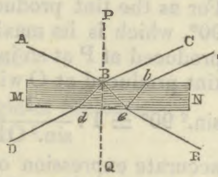
These measures are calculated for the *yellow* rays.

Sect. IX.—*On the System of Rings produced by Biaxal Crystals.*

The biaxal system of rings was discovered by Sir David Brewster, while he was looking along one of the axes of *topaz* when the crystal happened to reflect the light of a part of the sky which was partially polarised, so that they were seen without the aid either of a polarising or an analysing plate.

Upon examining other minerals, he discovered that the possession of two systems of rings was the characteristic of by far the greater number of crystallized bodies. In some of the crystals, such as *topaz*, the lines along which each system of rings is seen are so much inclined to each other, that we cannot see the two systems at once; whereas in others, where the inclination of the lines is small, both the systems may be distinctly seen at the same time. This will be understood, in the case of topaz, from fig. 149, where MN is a plate of topaz with parallel faces of cleavage perpendicular to PQ, the principal axis of double refraction. If we expose this plate to polarised light, so that the polarised ray passes along the line ABeE (the plane of incidence being in one of the two neutral axes of the plate); and if the eye at A receives this ray *without* using the *analysing plate*, it will see in the direction of that ray a system of oval rings of extreme beauty, like that shown in Plate CCCLXXXIII. fig. 32. When the polarised light is transmitted along the line CB*d*D, equally inclined to the perpendicular PQ, it will see a similar system. The lines BD, B*e* are therefore the resultant axes of topaz, along which the double refraction vanishes. The angle ABC is about 121° 16′, but the inclination of the refracted rays or of the resultant axes is only 65°. Similar rings are seen by transmission in the direction D*d*, E*e*, but only *when the analysing plate* is used.

Fig. 149.



If we now receive the reflected ray upon the analysing plate at 0°, the system of rings will appear as in fig. 33, Plate CCCLXXXIII., which differs from fig. 32 only in the parts near the major axis. The colours are the same, but the central spots are much smaller, and the mass of darkness with which they are surrounded encroaches considerably upon the blue part of the first ring. The same system will be seen at 90°, 180°, 227°; but upon turning round the analysing plate, we shall see, at 45°, 135°, 225°, and 315°, a third set, shown in fig. 34, which is comparatively faint in its colour, but distinguished by its peculiarities. In its general structure it resembles the set in fig. 32, but in the middle of each central spot there is a darker spot, composed of blue and red chiefly, with a little green above the blue, and every ring is divided into two rings, each of which has the same colours as the original ring. This division of the rings occupies only a part of the semicircumference of each, and is not seen beyond the third ring. When the analysing plate begins to move from 0°, 70°, &c. where fig. 33 is seen, towards 45°, 135°, &c. two blue spots, and the division of the rings, begin to appear at A and A in all the rings, and in the two central spots, and move along each till they reach B at 45°, 135°, &c. Continuing to turn the analyser, the spots and divisions move onward from B to C in all the rings, &c., and disappear at C at 90°, 180°, &c. This curious system of rings is obviously the first set in fig. 32, seen at the same time with their complementary rings, and is a very rare phenomenon.

Polarisation.

Rings in nitre.

The biaxal system of rings is best seen in *nitre* or *saltpetre*, in which the inclination of the resultant axes is only about 5°, or forming an angle of $2\frac{1}{2}$ with the axis of the six-sided prism. When a plate of nitre, about the sixth or eighth of an inch thick, is placed before a small analysing plate, and very close to it, and the eye also held as close to the analysing plate as possible, we shall see the beautiful biaxal system of rings discovered by Sir David Brewster, and shown in Plate CCCLXXXIII. fig. 35, where the plane passing through the two axes of nitre is parallel or perpendicular to the plane of primitive polarisation. At angles inclined 45° to these planes, the rings assume the form shown in fig. 36. In passing from the one of these states to the other, the rings assume the forms shown in figs. 37 and 38. The colours begin at the centres A and B of each system; but at a certain distance, varying with the thickness of the plate, the rings, in place of returning and encircling each pole, encircle the two poles, as an ellipse does its foci. When the thickness of the plate is very small, the rings enlarge, and the fifth ring will surround both poles. At a less thickness the fourth, and so on, till at a very small thickness the first ring, will surround both poles, and the system then resembles much the uniaxal system of rings. If the plate of nitre is very thick, the rings diminish in size. These colours deviate more and more from those of Newton's scale, and the tints do not begin at the poles A and B, but at virtual poles in their vicinity. The colours of the rings within the two poles are *red*, and beyond them *blue*, and the great body of the rings is pink and green. The rings have been called *isochromatic lines*, or *lines of equal tint*; and the axes passing through the poles A, B, *optical axes*, or *axes of compensation*, or *resultant axes*.

We have already given a long list of the various minerals and crystals which exhibit the biaxal system of rings, and also the position of the line which bisects the angular distance between the resultant axes, which is the *principal axis* of the crystal.

The following table, showing the inclination of the resultant axes in different crystals, was drawn up from the observations of Sir David Brewster. Several observations by other observers have been added.

Names of Minerals.	Character of Principal Axis.	Inclination of Resultant Axis.	
Glauberite	Negative	2° or 3°	0′
Sulphate of nickel, certain specimens	Positive	3	0
Carbonate of strontites	Negative	6	56
——— barytes	Ditto		...
Nitrate of potash	Ditto	5	20
Mica, certain specimens	Ditto	6	0
Talc	Ditto	7	24
Carbonate of lead	Ditto	10	35
Sulphato-carbonate of lead	Ditto	10	30
Mother-of-pearl	Ditto	11	28
Hydrate of barytes	Ditto	13	18
Mica, certain specimens, about	Ditto	14	0
Arragonite	Ditto	18	18

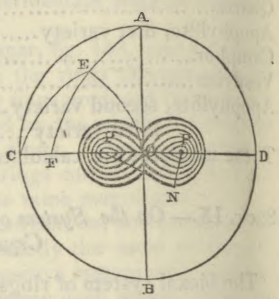
Polarisation.

Names of Minerals.	Character of Principal Axis.	Inclination of Resultant Axis.
Pyroxene (Miller)		19° 30′
Prussiate of potash, certain specimens	Positive	19 34
Cymophane	Ditto	27 51
Borax	Ditto	28 42
Anhydrite[1]	Ditto	28 7
Mica (Biot)		30 to 37 0
Apophyllite, *biaxal*	Negative	35 8
Sulphate of magnesia	Ditto	37 24
——— barytes	Positive	37 42
Spermaceti, about	Ditto	37 40
Tincal, or native borax	Negative	38 48
Nitrate of zinc, estimated at about		40 0
Stilbite	Positive	41 42
Sulphate of nickel	Ditto	42 4
Tartrate of ammonia (Miller)	Negative	42 20
——— (Herschel)		45 0
Carbonate of ammonia	Negative	43 24
Anhydrite (Biot)		44 41
——— (Herschel)		43 48
Mica	Negative	45 0
Lepidolite	Ditto	45 0
Benzoate of ammonia	Positive	45 8
Sulphate of zinc	Negative	44 28
——— magnesia and soda	Positive	46 49
Hopeite	Negative	48 0
Brazilian topaz	Positive	49 50
Sulphate of ammonia	Ditto	49 or 42 0
Sugar	Negative	50 0
Sulphate of strontites	Positive	50 0
Murio-sulphate of magnesia and iron	Negative	51 16
Sulphate of ammonia and magnesia	Positive	51 22
Heulandite (Herschel)		54 17
Phosphate of soda	Negative	55 20
Comptonite	Positive	56 6
Felspar	Negative	58 30
Sulphate of lime	Positive	60 0
Oxynitrate of silver	Ditto	62 16
Dichroite or iolite	Negative	60 50
Topaz (Aberdeenshire)	Positive	65 0
Sulphate of potash	Ditto	67 0
Carbonate of soda	Negative	70 1
Acetate of lead	Ditto	70 25
Citric acid	Positive	70 29
Tartrate of potash	Negative	71 20
Benzoic acid (Miller)	Ditto	75 0
Tartaric acid	Ditto	79 0
Sulphate of oxide of iron and ammonia (Miller)		79 0
Tartrate of potash and soda	Positive	80 0
Carbonate of potash		80 30
Kyanite	Positive	81 48
Hyper-oxymuriate of potash		82 0
Muriate of copper		84 30
Epidote, about		84 19
Peridot		87 56
Crystallized Cheltenham salts		88 14
Hyposulphate of soda (Marx)		89 20
Succinic acid, estimated at about		90 0
Sulphate of iron, about		90 0

Many of the measures in the preceding table were taken with much care; but some of them were only estimated, and others will admit of correction by the use of better specimens than the author was able to procure.

In order to explain the biaxal system of rings, and to discover the law of the tints by which every point of the complex system of rings can be calculated, Sir David Brewster considered the *optic or resultant axes* P, P′ as produced by two or more rectangular axes, the principal one passing through O, and the other two at AB and CD. We shall suppose, however, the most simple case, where the axes are only *two*, viz. that at O, and another either coinciding with AB or CD, perpendicular to O. Now, if O is a *negative* axis, AB must also be *negative;* but if we take CD for the other axis, it must be *positive;* for as the axis CD compensates the *negative* axis O at P, acting in the same plane, it must be a *positive* axis, for a negative axis would have united its effect with that of O. For a similar reason, the axis at AB must be *negative*, in order to compensate the *negative* axis O in a plane at right angles to it.

Fig. 150.



Supposing, then, O and AB to be two *negative* axes, as in *mica*, let it be required to determine the system of rings which they will produce, or the *tint* at any point F. Now we may either assume the relative intensities of these axes, or, what is better, the angle formed by the two poles P, P, where the actions of the two axes are compensated, as this angle can be readily measured in any crystal. As the action of the axis AB (or the tint which it produces) at P is destroyed or compensated by the action of the axis O, or the tint which it produces, and as the tint is proportional to the square of the sine of the angle which the ray makes with the axis, it is evident that the intensity of the axis at O must be to the intensity of AB, as 1 to $\frac{1}{\sin.^2 OP}$. For as the tint produced at P by AB at an inclination of 90°, which is its maximum tint, is equal to the tint of O produced at P at an inclination equal to OP, the *maximum* tint produced at O will be found thus: $\sin.^2 OP : \text{rad.}^2$ or $\sin.^2 90° = 1 : \frac{1}{\sin.^2 OP}$. We have therefore obtained an accurate expression of the relative intensities of the two negative axes O and AB.

If we had supposed the rings to be produced by a *negative* axis O and a *positive* one CD (which would equally account for the phenomena), then the intensity of O will be to that of CD as $\cos.^2 OP$ is to $\sin.^2 OP$.

From a great number of observations made at all inclinations to the resultant axes, and from accurate measurement of the projected rings, Sir David Brewster found that all the phenomena of the rings, with all their varieties of form and curvature, were represented by the following law.

The tint produced at any point of the sphere, by the joint action of two axes, is equal to the diagonal of a parallelogram whose sides represent the tints produced by each axis separately, and whose angle is double of the angle formed by the two planes passing through that point of the sphere and the respective axes.

In showing the application of this law, let it be required to find the tint produced at E, fig. 150, by the joint action of the two axes O and AB, whose relative intensities are as 1 to $\frac{1}{\sin.^2 OP}$. Through E draw three great circles AEF, CE, and OE; then let

[1] This must have been a different mineral from that examined by Biot.

Polarisation.

$T =$ tint required at the point E;
$\theta =$ the arch between the point E and the axis O;
$\varphi =$ the arch between the points E and C;
$a =$ the tint produced separately at E by the greater axis;
$b =$ the tint produced separately at E by the lesser axis;
$\psi =$ the angle of the forces;
$\pi =$ the angle CEF;
$\omega =$ the angle OEF;
$A =$ the arch FO, or the angle OAF, or the *azimuth* on the great circle CPO passing through the poles P, P, or centres of the two systems of rings;
$D =$ the arch FE, or the declination or distance of the point E from the same great circle;
$\zeta =$ half the difference of the angles at the base or at the diagonal of the parallelogram of forces.

Then we have

$$\cos.\ \theta = \cos.\ A \times \cos.\ D,$$
$$\varphi = 90° - D,$$
$$\cos.\ \omega = \frac{\tan.\ D}{\tan.\ \theta},$$
$$\cos.\ \pi = \frac{\tan.\ D}{\tan.\ \varphi},$$
$$2\ AEO = \psi = 2\,(180° - \omega) = 2\,\omega.$$

Since, then, the tints a, b produced at E by the axes O and AB are as the squares of the sines of the distance of E from these axes, or as $\sin.^2$ OE and $\sin.^2$ AE, and as the relative intensities of the axes are as 1 to $\frac{1}{\sin.^2 OP}$, we shall have

$$a = \sin.^2 OE, \text{ and } b = \sin.^2 AE \times \sin.^2 OP.$$

Having thus found the sides of the parallelogram of forces whose angle is ψ, the diagonal T of this parallelogram, or the *compound tint* at E, will be obtained in the following manner:

$$\text{Tan. } \zeta = \frac{a - b \tan. \frac{1}{2}\psi}{a + b}, \text{ and}$$
$$\zeta + \tfrac{1}{2}\psi = \text{greater angle at the base.}$$
$$\text{Hence } T = \frac{a \sin.\ \psi}{\sin.\ \zeta + \frac{1}{2}\psi}.$$

When $a = b$, $T = 2a\,(\cos.\ \pi + \omega)$.
When $a = b$ and the two axes O, and AB equal $\pi = \omega$ and $T + 2a\,(\cos.\ 2\pi)$.
When twice the angle formed by the planes OE, AE or

$$\psi = 90°, \text{ then } T = \sqrt{a^2 + b^2}.$$

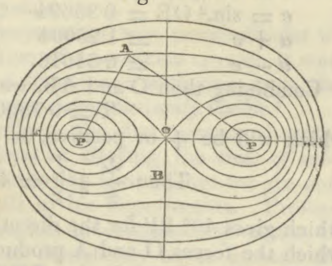
When $\psi = 180°$, $T = a - b$.
When $\varphi = 0°$ or $360°$, $T = a + b$.

Such is the method of determining the tints, and consequently the form of the isochromatic curves in relation to the real axes to which the forces refer; but in relation to the poles P, P, the law of the tints may be more simply expressed by the formula $T = t \sin.\ PE \times \sin.\ P'E$, where t is the maximum tint at A, which must be previously determined. This rule was deduced by M. Biot mathematically from Sir David Brewster's law, and it was afterwards established experimentally by Sir John Herschel, without being aware of its having been deduced from the general law.

The preceding general law is equally applicable when the rings are formed in homogeneous light.

Sir John Herschel,[1] in examining the systems of biaxal rings, found that they resembled lemniscates, as represented in the annexed figure. In these curves the rectangle $PE \times P'E$ is invariable throughout each curve, and the value of this constant rectangle in any one curve is $a \times b$, b being the parameter of the curve, and a half the distance between the poles P, P. The quantity a is of course the same for each curve, but b in different curves increases in the arithmetical progression 0, 1, 2, 3, &c. for the several dark intervals of the rings, beginning at the poles, and in the progression $\frac{1}{2}$, $\frac{3}{2}$, $\frac{5}{2}$, &c. for the brightest intermediate spaces.

Fig. 151.



Many interesting conclusions have been deduced from the preceding general law by Sir David Brewster. When the two *negative* axes O and AB, fig. 150, are of equal intensity, then their action will be compensated at C and D, and C D will be a single *positive* axis of double refraction, and also of an uniaxal system of rings like those in *zircon;* and the isochromatic curves given by the preceding formulæ will be circles surrounding the axis. Hence it follows, *that two negative rectangular axes of double refraction and polarisation compose a single positive axis.* If we now suppose a negative axis at CD, equal in intensity to any of the other two, it will evidently destroy the *positive* axis of compensation at CD, so that three equal and similar *negative axes in any crystal destroy each other;* and hence our author was led to the conclusion, that all the tessular crystals in which there was neither double refraction nor polarisation had three such axes. But if the *third* axis at CD is not equal to O or AB, and if O and AB are unequal, then we shall have all the phenomena of a crystal with two axes. In order to compute the tints thus produced by *three* unequal axes, let O, AB', and CD be three axes, and P, P' the centres of the double systems of rings which they produce. We have already shown that the resulting tint of two axes O and AB, at any part E, is

$$T = \frac{a \sin.\ \psi}{\sin.\ \zeta + \frac{1}{2}\psi}.$$

In order, however, to combine this tint with another, we must know the direction of it. Since ψ is the double of the real angle of the planes in which the forces from O and AB act, the direction of the new plane in which these forces act must form an angle with the real direction of O, whose complement is

$$\frac{\frac{1}{2}\psi + \zeta}{2} \text{ or } \frac{\psi}{4} + \frac{\zeta}{2},$$

or it forms with the real direction of A an angle whose complement is

$$\frac{\frac{1}{2}\psi - \zeta}{2} \text{ or } \frac{\psi}{4} - \frac{\zeta}{2}.$$

Hence the direction of the resultant in relation to BE, the direction of the third force with which it is to be combined, is known.

In order to illustrate this in a case where the truth of the result will be immediately seen, we shall take the case of three equal axes, the general resultant of which is *nothing.* In fig. 150, let O, AB, and CD be the three equal axes, and E the point where we require to know the effect of their combined action. Take AE = 70°, CE = 60°, then EG = 30°, EF = 20°, AG = 66° 44', OG = 23° 16', OE = 37° 17'; then

[1] Treatise on Light, sect. 903.

Polarisation.

$$a = \sin.^2 AE = 0{\cdot}883104 \qquad \psi + \begin{cases} 237^\circ\ 16' \\ 122^\circ\ 54' \end{cases}$$
$$b = \sin.^2 CE = 0{\cdot}7500 \qquad \zeta = \ 37^\circ\ 12'$$
$$c = \sin.^2 OE = 0{\cdot}36694 \qquad \omega = \ 40^\circ\ 4'$$
$$a + c \quad = 1{\cdot}25004 \qquad \pi = \ 77^\circ\ 52'$$
$$a - c \quad = 0{\cdot}51616.$$

Combining then O and AB, we shall have

$$T = 0{\cdot}7500,$$

which will be + or positive, as ψ is greater than 180°.

$$\text{Then } \frac{\psi}{4} + \frac{\zeta}{2} = 49^\circ\ 19',$$

which gives 40° 21′ for the direction of the new plane in which the forces O and A produce the combined tint of 0·7500. But the angle ω or OEG = 40° 41′, so that the resultant lies in the plane CEG; and hence, if we combine with this resultant, or + 0·7500, the force — 0·7500, produced by CD, the result will be *nothing*. This method is also applicable to the combination of axes of double refraction, the numbers corresponding to *a*, *b*, *c* being in that case the difference between the squares of the velocities of the ordinary and extraordinary rays, as produced by each axis separately at the point E.

The following table of the intensities of the polarising force in biaxal crystals has been given by Sir John Herschel:

	Value of the Highest Tint.	Thicknesses that produce the same Tint.
Nitre	7400	0·000135
Anhydrite, angle of axis 43° 48′	1900	0·000526
Mica, angle of axes 45°	1307	0·000765
Sulphate of barytes	521	0·001920
Heulandite (white), angle of axes 54° 17	249	0·0004021

The numbers belong to the *yellow* ray.

Sect. X.—*On Conical Refraction in Biaxal Crystals.*

Conical refraction.

The phenomenon of conical refraction seen along the axes of biaxal crystals was deduced by Sir W. Hamilton from the undulatory theory, and was discovered experimentally and examined by Professor Lloyd in *arragonite*. It followed from the theory, that a single ray, proceeding from a point within the crystal, and emerging at each of the four poles, must be divided into an *infinite number* of emergent rays, constituting a conical surface; and that a single ray incident externally would be similarly divided.

In order to examine the emergent cone formed in air, Professor Lloyd placed a lens of short focus at its focal distance from the first surface of a plate of *arragonite* 0·49 of an inch thick, having its parallel faces perpendicular to the principal axis of the crystal, and so that the central part of the pencil might have an incidence nearly parallel to the optical axis. He then looked through the crystal at the light of a lamp placed at a considerable distance, and observed a point more luminous than the space around it, having a sort of stellar radiation. In order to examine this phenomenon, he placed a plate of thin metal, having a minute aperture, on the surface of the crystal next the eye, and adjusted the aperture so that the line connected with the luminous point on the first surface might be in the direction of the optical axis. When the adjustment was complete, there appeared at first a luminous circle with a small dark space in the centre, and in this dark central space were two bright points, separated by a narrow and well-defined dark line, as shown in Plate CCCLXXXIV. figs. 39 and 40. When the aperture in the plate was slightly shifted, the phenomena rapidly changed, assuming successively the forms shown in figs. 41, 42, 43. In the first stage of the change the central dark space became greatly enlarged, and a double sector appeared in the centre. The circle was reduced to about a quadrant, and was separated by a dark interval from the sector just mentioned. This is shown in fig. 41. The remote sector then disappeared, and the circular arch diminished, as in fig. 42; and as the inclination of the internal ray to the optical axis was farther increased, these two luminous portions merged gradually into two doubly-refracted pencils. This change is shown in fig. 43. In these experiments the emergent rays were received directly by the eye placed close to the aperture on the second surface.

Professor Lloyd succeeded in showing the phenomena on a screen with the sun's light, and he found the light sufficiently distinct when the diameter of the section was one and a half inch. Upon examining the cone with a tourmaline, Professor Lloyd was surprised to observe that one radius only of the circular section vanished in a given position of the tourmaline, and that the ray which disappeared ranged through 360°, as the tourmaline was turned through 180°, the rays of the cone being all polarised in different planes. Upon a more attentive examination he discovered the remarkable law, "*that the angle between the planes of polarisation of any two rays of the cone is half the angle between the planes containing the rays themselves and the axis.*" The angle of the cone was found to be 6° 24′, 5° 56′, and 6° 22′; the mean of which is 6° 14.

When the aperture was considerable, such as that formed by a large-sized pin, two concentric circles were seen to surround the axis, the inner one being nearly twice as bright as the outer one, and consisting of unpolarised light, while the outer one was polarised according to the preceding law. By using smaller apertures the inner circle grew less, until it became a point in the centre of the fainter exterior circle, which remained fixed. With a still less aperture a dark space sprung up in the centre, increasing as the aperture diminished, until, with a very minute aperture, the breadth of this central space increased to about three fourths of the entire diameter. In these cases the appearances are as shown in figs. 44 and 45. When the line joining the luminous point on the first surface was slightly inclined to the axis, the appearance was that shown in fig. 46.

Professor Lloyd observed an interesting variation in the phenomena, by substituting a *narrow linear aperture* for the circular one on the first surface of the crystal, this aperture and the one in the plate next the eye being in the plane passing through the optic axes. The line had the appearance shown in fig. 47, swelling out into the form of an oval curve round the optical axis. By using a very minute aperture next the eye, the phenomenon was as shown in fig. 48. When the plate next the eye was slightly shifted, so that the plane passing through the aperture did not coincide with the plane of the optic axes, the curves rapidly changed, preserving, however, the form of the conchoid, whose pole was the projection of the axis of the emergent cone, and asymptote the line on the first surface. These effects are represented in figs. 49 and 50.

The second kind of conical refraction deduced theoretically by Sir W. Hamilton takes place when a single external ray is incident upon a biaxal crystal, so that one refracted ray coincides with an optic axis. In this case there should be a cone of rays within the crystal, the angle of the cone in arragonite being 1° 55′. As this cone will have its rays refracted at emergence, in a direction parallel to the incident ray, they will form a small cylinder of rays in air, the character of whose section by the surface of emergence being only 1° 55′ at a distance equal to the thickness of the crystal.

In order to detect the existence and measure the size of this cylinder, Professor Lloyd used the light of a lamp placed at some distance, and he made its light pass through two small apertures placed in a straight line, the

Polarisation.

one in a screen near the flame, and the other in a plate of metal close to the first circle of the crystal. Under ordinary circumstances, the incident ray will be doubly refracted within the crystal, and the two pencils will emerge parallel to the second surface. Professor Lloyd was able to distinguish these two pencils by means of a lens; and turning the crystal slowly, so as to vary the incidence, he observed a position in which the two rays changed their relative places rapidly on any slight change of incidence, and appeared at times to revolve round one another as the incidence was changed. Being convinced that the ray was now at the critical incidence, Professor Lloyd changed the position of the crystal relative to the incident ray very slowly; and after much care in the adjustment, he at last saw the two rays spread into a continuous circle, and exhibit the phenomena which we have already described in his own words in our history of Optics.

Professor Lloyd measured the angle of the cone by an indirect method, and found it 1° 50′, differing only 5′ from the angle deduced from theory.[1]

Sect. XI.—*On the Effect of Pressure and Heat on the Double Refraction of Crystals with One, Two, and Three Axes.*

Influence of pressure.

The influence of pressure and heat in modifying the doubly-refracting structure of bodies that previously possessed that property, and of creating a new doubly-refractive structure in uncrystallized bodies, was first studied by Sir David Brewster.[2]

By applying compressing and dilating forces to minerals, he succeeded in altering their doubly-refracting structure in every direction; but the effect was always most easily seen when it was produced along the real axes of uniaxal crystals, or the resultant axes of biaxal ones, where the effect of the natural forces was either nothing, or compensated. The following were some of the results to which he was led by applying the forces to parallel surfaces.

Axis of Compression and Dilatation parallel to the Axis of the Crystal.

Positive crystals....	Compressed...	Tints rise in Newton's scale.
	Dilated.........	Tints descend in Newton's scale.
Negative crystals...	Compressed...	Tints descend in Newton's scale.
	Dilated.........	Tints rise in Newton's scale.

Axis of Compression and Dilatation perpendicular to the Axis of the Crystal.

Positive crystals....	Compressed...	Tints descend in Newton's scale.
	Dilated.........	Tints rise in Newton's scale.
Negative crystals...	Compressed...	Tints rise in Newton's scale.
	Dilated.........	Tints descend in Newton's scale.

The axis of compression and dilatation is the line perpendicular to the two surfaces pressed together or drawn asunder.

The above results were obtained by experiments both on uniaxal and biaxal crystals.

When the axis of compression was perpendicular to the axis of double refraction of an *uniaxal* crystal, it was partially converted into a biaxal one with two axes, *the poles of the two resultant axes being distinctly visible.*[3]

Influence of heat.

M. Fresnel was, we believe, the first person who observed the influence of heat in altering the *tints of sulphate of lime* perpendicular to the laminæ, but we are not able to refer to the details of his experiments. Professor Mitscherlich, however, has investigated the action of heat upon this mineral so completely as to include all previous experiments in his results. Having found that heat acts upon calcareous spar differently in different directions, expanding it in the direction of its axis, and slightly contracting it in directions perpendicular to the axis, he sought to determine if any variation in the double refraction was produced by heat. By the method of interferences, and observing the compensation produced by crossing plates of crystals at different temperatures, he observed that a change in the double refraction was produced.

Mitscherlich.

In extending these experiments, Professor Mitscherlich found that the two resultant axes of sulphate of lime inclined 60° to each other at common temperatures, approached each other when heated, till they met, and constituted one axis of double refraction. By increasing the heat they again separated *in a plane perpendicular to the laminæ.* In this experiment the principal axis of double refraction which bisected the optic axes gradually increased, while the second real axis perpendicular to the laminæ diminished and disappeared when the crystal assumed the uniaxal state. A new axis then sprung up in the plane of the laminæ perpendicular to the principal axis.

Sir John Herschel.

Sir John Herschel, in mentioning this remarkable experiment, states that he observed the tints of a plate of sulphate of lime *rise* rapidly in the scale when the plate was moderately warmed by the heat of a candle held at some distance below it, and sink again when the heat was withdrawn. He found, on the contrary, "that mica similarly heated undergoes no apparent change in the position of its axes, or in the size of its rings, though heated nearly to ignition."[4]

Recent experiments.

The extraordinary experiment of Professor Mitscherlich was repeated by Sir David Brewster with one of the specimens of sulphate of lime, in which he discovered one of the resultant axes of this mineral. The following is the account which he has given of this experiment, and of the discovery of a still more curious property in *glauberite.*[5] "The specimen of sulphate of lime was about one and a half inch thick in the plane of the laminæ, and the system of rings which surrounded this axis was exceedingly minute, with the usual black brush at each end of them. The other system of rings could not be seen in this specimen, owing to the manner in which it was cut. Having brought the crystal to a considerable heat, and exposed it to polarised light, it was a singular sight to see the system of rings travelling along towards the line which bisects the optic axes, like a celestial body passing through the field of a telescope, and changing their form and size as they advanced. The specimen did not permit me to see the two systems unite, and still less to see them open out

Polarisation.

again in a plane at right angles to the laminæ; but from the degree of heat which I used, and which drove off the water of crystallization from part of the specimen, I presume that the complete phenomenon cannot be developed without destroying the constitution of the crystal; that is, that after the two systems of rings have opened out in a new plane, they will not return, by cooling, through their state of union, into their primitive inclination of 60° in the plane of the laminæ.

"A property of a similar kind, but perhaps a still more extraordinary one, I discovered some years ago, subsequent to Professor Mitscherlich's discovery; and I have slightly noticed it in a paper on glauberite, published in the Edinburgh Transactions.[1] This interesting mineral has at ordinary temperatures the curious property of *two axes of double* refraction for *red* light, and only *one axis* for *violet* light. If we apply heat to it, the two optic axes for red light gradually close, and, at a temperature which the hand can endure, the two systems of rings for red light have united into one system, so that the crystal has now only one axis of double refraction for red light. By continuing to increase the heat, the two axes separated, and the single system of rings opened out into two systems, lying in a plane at right angles to that in which they were placed at first. The heat was now less than that of boiling water. By increasing it, the inclination of the optic axes gradually increased.

"I now applied artificial cold to a crystal of glauberite at the ordinary temperature of the atmosphere. The inclination of the optic axes for red light increased, as might have been predicted; but, what was very unexpected, a *new axis was created for violet light*, the plane of the two violet axes being coincident with the plane of the two red optic axes at and below the ordinary temperature. An increase of cold increased the inclination of the optic axes for all the colours of the spectrum; the inclination of the axes being *least* for the *most refrangible*, and *greatest* for the least refrangible rays.

"These results appear very complicated when we begin with the effects at an ordinary temperature, and view them in the manner in which they were observed; but if we commence the experiments at a low temperature, such as the freezing point, the order and connection of the phenomena will be more easily understood.

"At 32° glauberite has two axes of double refraction for rays of all colours, the inclination of the axes for the violet rays being least, and that for the red the greatest. As the temperature rises, the optic axes for all colours gradually approach, and the axes for violet first unite into one. At this time the crystal has two axes for all the other colours; but as the heat increases, all the other pairs of axes unite in succession, and form a single system of rings. But before this has taken place, the axes for violet rays have opened up again in a plane at right angles to that in which they originally lay, and they are followed by all the other pairs of axes; so that at a temperature much below that of boiling water, each pair of axes appears with different inclinations arranged in a new direction.

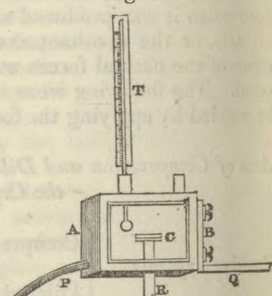
"During all the changes which have been described above, the crystal has preserved its constitution; and by abstracting the heat, the phenomena are all repeated in an inverse order.

"If the crystal should happen to be observed at that temperature, which very often occurs when the greenish-yellow or most luminous rays have the optic axes corresponding to them united, or form a single system of rings, then the blue rays will have two systems of rings lying in one plane, and the red rays also two systems of rings in a plane at right angles to this. In two rectangular positions, namely, when the planes of the double axes coincide with or are at right angles to the plane of primitive polarisation, the black cross will be very distinct; but in intermediate positions it will be much less so, and the uniaxal system of rings which predominates, from the greater intensity of their light, will have that indistinctness of character which, whenever it occurs, indicates a peculiar action of the doubly-refracting force on the differently-coloured rays. When the black cross is perfect and equally distinct in all positions, while the colours of the rings deviate from those of Newton's scale, then the axes for all colours are obviously coincident, and the peculiarity in the colour of the rings is owing to an irrationality in the action of the doubly-refracting forces on the differently-coloured rays."

A series of highly valuable experiments on the changes which temperature produces in the double refraction of crystals,[2] have been made by Professor Rudberg of Upsal. Professor Mitscherlich having only determined the ratio between the mean double refraction of Iceland spar in a cold and in a heated state, without ascertaining the separate variations in each pencil, Professor Rudberg was desirous of supplying this desideratum.

For this purpose he constructed a box, AB, having four of its faces double, so as to enclose a space which received through the pipe P, and retained, the steam from a boiler. This space communicated also with the external air. The other two faces of the box were formed with plates of mica. The inner box, therefore, contained only air, which was heated by the surrounding steam. A thermometer T indicated the temperature of the air. A tube R, passing through the two lower surfaces of the box, formed a free communication between the interior and the exterior air, so that their elasticity was the same. Through this tube R, without touching its sides, there rose from the centre of the repeating circle a vertical copper rod, carrying a plate C, upon which the crystal was placed. This rod was attached below to another plate of copper, which rested on a ring of copper, which, having teeth upon its circumference, could be moved by a screw. By this arrangement he could perform the experiments as readily as if there had been no heating apparatus to obstruct them. The heating apparatus was attached by a rod Q of iron rising from the masonry on which the repeating circle rested.

Fig. 152.



The experiments were made to determine the index of refraction of the ray F of Fraunhofer's spectrum near the boundary of the *green* and *blue* spaces. In this way he obtained the following results.

1. Calcareous Spar. Refracting angle of prism 59° 55′ 9″.

a. Ordinary Ray. The minimum deviation of the line F produced by the prism was 52° 53′ 43″. With a difference of temperature of 64° (Reaumur, we presume), this ray suffered no change in its deviation; from which our

[1] Edin. Trans. vol. xi. part ii. page 273.

[2] This interesting paper was communicated by the author to Sir David Brewster, and published in the London and Edinburgh Philosophical Magazine, December 1832, vol. i. p. 409.

author concluded, *that the refractive power of* CALCAREOUS SPAR *for the ordinary ray either does not change at all with the temperature*, or decreases with it by a quantity *extremely small*. The index of refraction of F at the ordinary temperature was 1·66802.

b. Extraordinary Ray. By the difference of temperature of 64°, the deviation was increased 2′ 26″, or 2′ 34″ when corrected, which gives for the index of refraction,

1·49118 at 64°
1·49075 at ordinary temperature

0·00043 increase.

Polarisation.

Hence, *in the extraordinary ray, a rise of temperature of* 64° increases the index of refraction 0·00343.

Professor Rudberg confirmed this result in the presence of Professor Mitscherlich in 1832.

Rock crystal.

2. ROCK CRYSTAL. Refracting angle of prism 45° 20′ 5″.

In both the ordinary and extraordinary ray, the deviation was *decreased* by a rise of temperature 42″. The indices for the ray F became in the extraordinary ray 1·55868, being 0·00028 more than at the ordinary temperature; and in the ordinary ray, 1·54944, being 0·00026 less.

Arragonite.

3. ARRAGONITE. With four prisms he obtained the following results.

	Prism, No. 1.	No. 2.	No. 3.	No. 4.
Variation of the deviation	— 5′ 8″	— 1′ 53″	— 4′ 3″	— 2′ 58″
Variation of refracting angle	...	+ 16″	— 1′ 53″	— 48″·6

When corrected for the deviation of the plate of mica, they became

Variation of deviation	— 1′ 47″	— 3′ 57″	— 2′ 52″
Variation of angle	+ 30 0	— 1 44	— 40″

Hence he obtained the following indices of refraction:

	No. 2.	No. 3.	No. 4.
At ordinary temperature	1·53478	1·69510	1·69058
At increased temperature	1·53416	1·69421	1·68976
Changes on index	— 0·00062	— 0·00089	— 0·00082

Hence, says our author, *the double refraction of arragonite appears to decrease a little with the temperature*, because the refracting power in the direction of the axis A has diminished in a smaller ratio than that along the axes B and C. In other respects arragonite comports itself quite differently from calcareous spar. The axis A of arragonite obviously corresponds with the axis of crystallization of the spar; but notwithstanding this, the refractive power in this direction diminishes in the former, and, on the contrary, increases in the latter, besides, that in the direction perpendicular to the axis A, the refractive power diminishes considerably in arragonite, whilst, on the contrary, it undergoes almost no change in calcareous spar.

Regular double refraction produced by pressure.

While heat and pressure thus modify the doubly-refracting structure in minerals, they are capable of creating it with *regular axes* in several soft substances. This effect is quite different, as we shall soon see, from that which is produced upon bodies by pressure, where the result is modified by the external form of the body, and where the double refraction disappears when the heat or pressure is removed, or when the body is subdivided. A permanent change is induced upon the soft solids in question, and, when subdivided, each part of the mass or plate preserves the property communicated to it. Sir David Brewster described, in the Philosophical Transactions for 1815,[1] the original experiment which he made on this subject with a mixture of rosin and white wax; but in the same work for 1830,[2] he has given a detailed account of his experiments, and of the conclusions to which they lead respecting the origin of the doubly-refracting structure. The following is the fundamental experiment described by our author.

"I took a few drops of the melted compound (rosin and bees' wax), and placed them in succession on a plate of thick glass, so as to form a large drop. Before it was cold I laid above the drop a circular piece of glass about two thirds of an inch in diameter, and, by a strong vertical pressure on the centre of the piece of glass, I squeezed out the drop into a thin plate. This plate was now almost perfectly transparent, as if the pressure had brought the particles of the substance into optical contact.

"If we expose this plate to polarised light, we shall find that it possesses one *positive* axis of double refraction, and exhibits the polarised tints as perfectly as many crystals of the mineral kingdom. The structure thus communicated to the soft film by pressure does not belong to it as a whole, nor has it only one axis passing through its centre, like a circular piece of unannealed glass. In every point of it there is an axis of double refraction perpendicular to the plates, and the doubly-refracting force varies with the inclination of the incident ray to this axis, as in all regular uniaxal crystals.

"When the two plates of glass are drawn asunder, we can remove one or more portions of the compressed plate, and these portions act upon light exactly like plates of uniaxal mica or hydrate of magnesia, and develope a doubly-refracting force of nearly equal intensity."

Cause of double refraction.

By reasoning from this experiment, our author is led to the opinion that double refraction is acquired by the particles of bodies at the instant of their aggregation, and arises from the pressures produced in the direction of three rectangular axes, by the forces of aggregation. When these forces are very weak, double refraction will not be produced; when they are sufficiently strong and of equal intensity, they will produce tessular crystals; when they are equal in two rectangular directions, they will produce uniaxal crystals; and when they are unequal in all the three directions, they will form biaxal ones. In this way all the phenomena of cleavage may be readily explained.

Upon some substances heat performs the same part as pressure; but our limits will not permit us to detail our author's experiments on this subject.

SECT. XII.—*On the Deviation of the Polarised Tints from those of Newton's Scale.*

In all his investigations respecting the colours of thin plates, M. Biot happened to use only such crystals as

[1] Page 31, 32.

[2] Page 87.

Polarisation.

gave polarised tints similar to those of Newton's scale, and he therefore considered this to be their character. In 1813, however, when Sir David Brewster described the rings in topaz, he gave a list of all the colours in different azimuths round the optic axes, and he not only found these colours to vary in these different azimuths in the same ring, but observed some colours at the extremity of the optic axes. In his paper on the laws of polarisation, published in the Philosophical Transactions for 1818, he remarks, that "in almost all crystals with two axes, the tints in the neighbourhood of the resultant axes, when the plate has a considerable thickness, lose their resemblance to those in Newton's scale, as will be more minutely described in another paper." In April 1817 he communicated to the Royal Society of Edinburgh an account of the extraordinary system of rings in the apophyllite from the Tyrol, which consisted of *purple* and *yellow* light, like the residual colours arising from the combination of irrational spectra.

In examining the colours of the polarised rings in biaxal crystals, he was led to divide them into two classes, viz. 1. Those that had the *red* ends of the rings *inwards*, or between the resultant axes, and the blue ends *outwards*. 2. Those that had the red ends of the rings *outwards*, and the *blue* ends of the rings *inwards*.

The crystals in which the deviation is very striking are given in the following table.

Class 1.—*Red ends inwards.*

Nitre.	Carbonate of lead.
Sulphate of barytes.	Sulphato-bicarbonate of lead.
——— of strontites.	Hyposulphate of strontia (Herschel).
Tartrate of potash and soda.	
Phosphate of soda.	Tartrate of potash.
Arragonite.	

Class 2.—*Red ends outwards.*

Topaz.	Native borax.
Mica.	Sulphate of magnesia.
Anhydrite.	Arseniate of soda.

Unclassed.

Chromate of lead.	Superoxalate of potash.
Muriate of mercury.	Oxalic acid.
——— of copper.	Sulphate of iron.
Oxynitrate of silver.	Cymophane.
Sugar.	Felspar.
Crystallized Cheltenham salts.	Benzoic acid.
	Chromic acid.
Nitrate of mercury.	Nadelstein.
——— of zinc.	Hyposulphate of soda (Herschel).
——— of lime.	

Sir John Herschel found anomalous tints in hyposulphate of lime, and Vesuvian, both crystals with one axis, a circumstance which we ascribe to that axis being the resultant of three axes, two of which are equal.

In examining the rings formed by biaxal crystals, Sir David Brewster found that the black spot at the point of compensation was not in the centre of the rings, and the position of this spot for *topaz* is given in his table of these colours.[1]

Sir John Herschel's experiments.

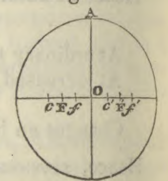
It is to Sir John Herschel, however, that we owe the complete investigation of this subject in reference to biaxal crystals. By using homogeneous light, he found that the angle of the resultant axes POp, fig. 129, was different for the different colours of the spectrum, varying, in the case of *tartrate of potash and soda*, from 75° 42′ in *red* light, to 55° 14′ in *violet* light, so that with *white* light we have a system of rings, consisting of five rings of all colours, overlapping each other, and these five constituting an irregular system, unlike those produced by ordinary crystals.

In crystals where the displacement of the rings is great, the *oval central spots* seen in Plate CCCLXXXIII. figs. 32, 33, and 34, are drawn out, as Sir John Herschel remarked, into long spectra or tails of *red*, *green*, and *violet* light, and the extremities of the rings are distorted and highly coloured, as in fig. 51, Plate CCCLXXXIV. When we view these spectra with coloured media, they are found to consist of well-defined spots of the several simple colours, arranged on each side of the principal section, as shown in fig. 52.

These results are capable of being rigorously calculated by the law of resultant axes given by Sir David Brewster, and may be considered as a proof of that law. If this were not the case, *tartrate of potash and soda* would have two axes for every different ray of the spectrum, and four series of poles extending each over a space of *ten degrees.*

In order to show how these phenomena may be calculated by two axes, let O and A, fig. 153, be two negative axes, which in *red* light compensate each other at F and F; then, if O and A had the same proportional action on the *violet* and other rays as on the *red* rays, F would also be the point of compensation for the *violet* and other rays. In this case F would be the centre of all the systems of rings, as in uniaxal crystals, and the tints those of Newton's scale. But if the axis O has a greater proportional action upon the violet and other rays than A, the point of compensation will be at f, which will be the centre of the violet system of rings, the centres of all the other systems being between F and f if the action of O upon them is of an intermediate nature. This is the case with all the crystals in Class 1 of the foregoing table. On the other hand, if O has a less proportional action on the violet than on the red, c, c will be the points of compensation for the *violet* rays, and the centres of the two systems of violet rings.

Fig. 153.



The most remarkable instances of deviated tints are those in *apophyllite*, a crystal with one axis, discovered by Sir David Brewster. Sir John Herschel, in examining a number of apophyllites, found that some specimens exercise *negative* action upon the rays at one end of the spectrum, a positive action upon rays at the other end, and no action at all upon the mean refrangible rays, the doubly refracting action ceasing, in the one case, in the yellow rays, and in another in the indigo.[2] In other specimens, the diameter of the rings was nearly the same for all the colours of the spectrum, and hence the rings were approaching to a series of black and white ones. All these phenomena may be separately calculated by the law of resultant axes already mentioned, on the supposition that apophyllite has three rectangular axes of double refraction. Sir David Brewster had discovered, in the tesselated apophyllite, portions which had *two* axes co-existing with portions that had *one* axis; and in his coloured drawings of the phenomena exhibited by this mineral, he has pointed out a most extraordinary law of symmetry which regulates its varying double refraction; and as he had shown that a double dispersive power existed in the same crystal, the following explanation of the remarkable phenomena of apophyllite approaches to the character of demonstration.

Let O be the positive axis of uniaxal apophyllite, and let A and B be two *positive* axes which, if equal, would produce a *negative* axis at O. But as the real axis at O is a positive one, the apparent or finally resultant axis at

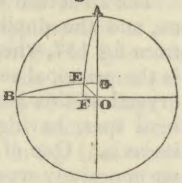
[1] Phil. Trans. 1814, p. 204, 205.

[2] Cambridge Trans. vol. i. p. 21-24.

Polarisation.

O will be a single axis, *negative* if the *negative* is the strongest, and positive if the positive is the strongest. Let us now suppose that the two axes at O have equal intensity, viz. $+ O = - O$ for *yellow* light ($- O$ being the resultant of $+ A$ and $+ B$), and that $- O$ acts more powerfully upon the *red* rays than $+ O$, while $+ O$ acts more powerfully upon the *violet* rays. In this case the two axes $+ O$, $- O$ will exactly compensate each other. In *yellow* light, a yellow ray will experience neither double refraction nor polarisation; whereas in *red* light, the predominance of $- O$ will leave a single negative axis for *red* rays, and produce a *negative* system of rings; and in *violet* light the predominance of $+ O$ will leave a single *positive* axis of double refraction for violet rays, and consequently a *positive* system of rings. This compensation resembles that of a compound lens, consisting of a *convex* and *concave* lens of equal curvature, of such a glass that their refractive index for *yellow* light is equal, while the index of refraction for the *violet* rays is *greater* in the *convex* lens, and the index for the *red* rays *greater* in the *concave* lens. Such a lens will *converge* the *violet* rays, *diverge* the *red rays*, and *produce no deviation* at all in the *yellow* ones; that is, the same compound lens will be a *plane* lens in *yellow* light, a *convex* one in *blue* light, and a *concave* one in *red* light. Hence each order of colours in apophyllite is as it were a secondary or residual spectrum arising from the opposite action of unequal negative and positive axes. From the fact of some apophyllites exercising a negative action, Sir David Brewster stated his expectation that apophyllites might be found in which the double refraction is negative for all the rays of the spectrum; and several years afterwards he discovered the remarkable mineral of *oxahverite*, which is an apophyllite with this property.[1]

Fig. 154.



The phenomena of glauberite already described afford an additional illustration of these views.

Sect. XIII.—*On Crystals with Planes of Double Refraction exemplified in Analcime.*

Analcime.

Analcime or *Cubizite*, a mineral which has been ranked among the cubical crystals, might have been expected to have had no double refraction if this had been its form. It was found, however, by Sir David Brewster, to be a singular body in its action upon light, and to exhibit the extraordinary property of many planes of double refraction, or planes to which the doubly-refracting structure was related in the same manner as it is to *one* or *two* axes in other minerals.

Analcime crystallizes most commonly in the form of the *icositetrahedron*, as in fig. 53, Plate CCCLXXXIV. If we suppose a complete crystal of it to be exposed to polarised light, it will give the remarkable figure shown in fig. 53, where the dark shaded lines are planes in which there is neither double refraction nor polarisation, the double refraction and the tints commencing at these planes, and reaching their maximum in the centre of the space enclosed by three of the dark lines. The tints are those of Newton's scale, and are negative in relation to each of the four axes of the *icositetrahedron*. When light is transmitted through any pair of the four planes which are adjacent to any of the three axes of the solid, it is doubly refracted, the least refracted image being the extraordinary one, and consequently the double refraction negative in relation to the axes to which the doubly-refracted ray is perpendicular.

If we suppose the crystal to have the form of a *cube*, the planes of double refraction will be, as in fig. 54, a plane passing through the two diagonals of each face of the cube.

The tints vary as the square of the distance from the nearest plane of double refraction.

The tints shown in figs. 53 and 54 cannot of course be seen at the same time, but are deduced from observations made by transmitting polarised light in every direction through the crystal.

Sect. XIV.—*On the Double Refraction and Polarisation of Composite Crystals.*

Composite crystals.

In all the crystallized bodies whose action upon light we have been considering, excepting *analcime*, the phenomena are identical in all parallel directions, the smallest fragment having the same property as the largest, from whatever part of the crystal it is taken.

In the mineral world, however, and among the products of artificial crystallization, there occur crystals which are composed of several individual crystals whose axes are not parallel. These crystals sometimes occur in such regular symmetrical forms, that mineralogists have long regarded them as simple forms; and it is probable that they would have still been viewed in this light, if they had not been exposed to the scrutiny of polarised light.

One of the most remarkable of these composite crystals is Iceland spar, some specimens of which were observed, even by Bartholinus and Huygens, to exhibit phenomena quite different from those which we have already described. The property which they possessed of multiplying the images of a luminous body seen through them had been carefully studied by Benjamin Martin, Professor Robison, Lord Brougham, Malus, and others; but until the publication of Malus' work on Double Refraction, no sound explanation was given of these remarkable phenomena.

Malus describes the phenomena as produced by fissures parallel to the surface of the variety of this mineral described by Haüy under the name of *chaux carbonatée equiaxe*. He explains the duplication of the images on the supposition that there is a *fissure* or real opening between the conjoined faces of the spar, and he ascribes the varying tints to a cause not adequate to the production of such splendid phenomena,—to the colouring of the thin plate of air included in the fissure. He states correctly, that the secondary images are doubled by *two* fissures, tripled by three, &c.[2]

This class of phenomena was particularly investigated by Sir David Brewster, who found that the fissures described by Malus *were thin crystallized laminæ of Iceland spar*, having their axes of double refraction inclined to that of the portions of the crystal which it separated; that these laminæ varied in thickness, the thinnest producing a large system of rings, and the thicker plates smaller systems, the plates being sometimes so thick that no colours whatever appeared. Hence it was obvious *that each crystal of this kind was a polarising and an analysing apparatus, the thin laminæ being the plate which exhibited its polarised tints in this singular position.*

In order to understand this remarkable structure, we have represented the laminæ in fig. 155 by the planes ABCD, *ebcg*, *afhd* parallel to the edges EGFH, and also to the long diagonals of the rhomboidal faces, or perpendicular to the short diagonal EF. When we look through a crystal with only *one* of these laminæ, we observe the two principal images of the candle A, B, or luminous

[1] Edinb. Journal of Science, No. xiii. p. 115.

[2] *Théorie de la Double Refraction*, p. 194–198.

Polarisation.

body, while at a vertical incidence, and separated just as they would have appeared in a common crystal of the same thickness. But on each side of this double image is a single-polarised image C and D, C being polarised in the same plane as B, and D in

Fig. 155.

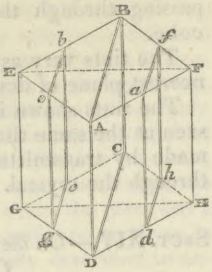


Fig. 156.

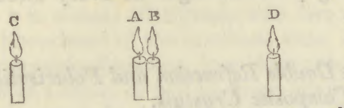


the same plane as A. Let us suppose that these phenomena are seen through a rhomb with only one plane ABCD (fig. 155), and through the faces EACD, BEHC. Then, if we incline the rhomb in different directions slightly, we shall see the images C, D disappear when they have a certain distance from A, B. If we incline the rhomb, bringing EA nearer the eye than CD, the images C, D will approach to AB, and will be found to disappear nearer and nearer to AB as the inclination is increased, it being necessary to bring the edge EG nearer the eye than AD, to make C and D disappear. While C and D are thus approaching to A, B, they become less and less coloured till they are all white. If we incline the rhomb in an opposite direction, so that GD is brought nearer the eye than EA, the images C, D recede from A, B, and become more highly coloured, the two images A, B becoming also coloured. The images C, D sometimes appear doubled when this inclination is going on, but it is only a duplicity of colour, so to speak, in consequence of the spectrum being divided by portions of it passing into the reflected pencil. When we bring EC nearer the eye than AD, the colours increase, A and B become also coloured, and an apparent colorific duplication of the images C and D takes place. If the rhomb is inclined in an opposite direction, so that AD is brought nearer the eye than EC, the images C, D become also at first more coloured; but by increasing the inclination, the image C recedes rapidly on the right side from A, B, contracts in breadth, and becomes prismatically coloured, the spectrum which it exhibits being subdivided by several black lines or bands, the parts of the spectrum corresponding to these black lines or dark bands having passed into the reflected ray. The spectrum D recedes as rapidly to the left, expanding in breadth, and even disappearing, as well as the images A, B.

All these phenomena are more finely seen, and the law of their changes more easily detected, if, instead of a candle, we look at a long line of light, such as the narrow opening between the edges of the window-shutters.

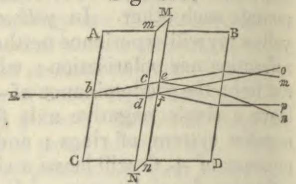
If we look through the faces ADFH, ADEG of the rhomb, placing a prism of glass with an angle of 12° or 15° upon one of the faces, to permit the refracted rays to emerge at a moderate angle of deviation, the prismatic images formerly described will be large spectra, subdivided by black spaces into 4, 5, 6, &c. coloured images of the candle, or of the long luminous line, exhibiting one of the most magnificent phenomena that can be witnessed.

These phenomena vary, of course, with the thickness of the enclosed laminæ, and as the laminæ increase in thickness the subdivisions of the spectral images become more numerous.

When we reflect light from these laminæ, ABCD, for example, by allowing the light to enter by the face BFHC, and emerge through the face AFHD, the boundary of total reflection is marked by a series of brilliant rectilineal fringes, polarised in the same manner as the image C, which is now the lowermost. When the light is transmitted through the laminæ at the boundary of total reflection, by entering through the face BECG, and emerging through AFHD, a series of rectilineal fringes complementary to the former reflected series is seen. They also are polarised in the same plane as C, or the lowermost secondary image, and become much more distinct, by causing the oppositely polarised pencil to disappear.

The structure which produces the preceding phenomena, and the duplication of the images, will be understood from fig. 157, where ABCD is the principal section of a crystal of this kind of Iceland spar, having AD for its axis. One of the laminæ oppositely crystallized is shown at M*m*, N*n*, but much thicker than they are generally, the angles A*m*M, D*n*N being 141° 44′. A ray of ordinary light R*b* will be refracted in the lines *bc*, *bd*. These rays entering the laminæ MN, will be again refracted doubly; but as the vein is so thin as to produce the system of uniaxal rings, the colours will vary with the thickness of the film and the inclination of the ray to the axis of the lamina. The four pencils will emerge from the lamina at *e*, *f*, and will be refracted again, as in the figure, into the pencils *em*, *en*, *fo*, *fp*, the colours of *en*, *fo* being complementary to those of *em*, *fp*.

Fig. 157.



That the multiplication and colour of the images are produced by the causes above explained, has been proved by Sir David Brewster, by actually placing laminæ of different crystals between the prisms AN, BN. In this way, by introducing different films in different azimuths, most beautiful combinations may be produced.

If we grind down the angles A and B, so as to have two faces perpendicular to the axis AB, the uniaxal system of rings is beautifully modified by the action of the lamina MN; and that this was the cause of the singular transformations which the rings experienced in different crystals, was proved by the author above quoted, by inserting laminæ between two plates of the *chaux carbonatée basée* of Haüy, whose natural faces are perpendicular to the axis. These transformations are exceedingly beautiful. Some of them are shown in figs. 55, 56, and 57, one of the rings consisting of eight dark radii, while the complementary system has its inner circle marked with *eight* dark-coloured spots. These rings suffer beautiful changes, both by the motion of the plane round its axes when the analysing plate is stationary, and by the motion of the analysing plate when the rhomb is stationary. In studying these phenomena in a great variety of crystals intersected with one or more laminæ, Sir David Brewster noticed a very remarkable fact. A rhomb of spar which produced in one part of it the transformed systems already mentioned, exhibited a singular effect in another part, where *the crystallization appeared perfect and simple*, and where there were decidedly no veins or laminæ. In one position or azimuth of this crystal, this portion gave, as might have been expected, the regular system of rings with the black cross shown in fig. 29. But upon turning it round 45°, all the rings became *elliptical*, as shown at ABCD in fig. 58, the *first* order of colours in one quadrant having joined the *second* order of colours in the adjacent quadrant. The arms of the black cross took the contorted position *abc*, *def*, the continuations of it afterwards, viz. *am*, *cn*, *do*, *fp* being so very faint as to show the continuity of the elliptical rings. In this figure the rings of the same order are marked with the same figure. The very same phenomenon, which points to important theoretical consequences, was observed by the same author in another rhomb of spar *wholly without veins*, but the rings were not so elliptical as in fig. 58.

This composite structure was discovered by Sir David

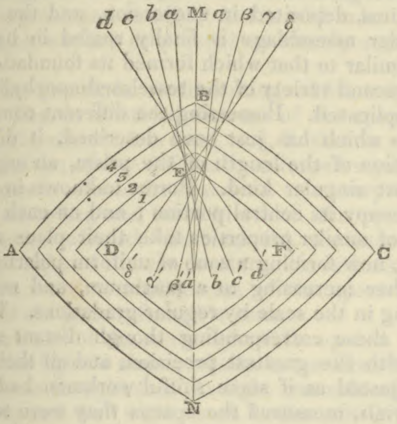
Polarisation.

Brewster in various minerals, and he has described it very minutely in the case of *Brazilian topaz, sulphate of potash*, and *apophyllite*.

Bra…n topa…

Sir John Herschel, we believe, first noticed this structure in Brazilian topaz, and observed that the central portion of the crystal had a different colour from the external portion, and that the plane of the principal section of the different parts made angles of 20 ±°. Sir David Brewster found very remarkable arrangements of the coloured portions, which he has represented in coloured drawings in the Cambridge Transactions, vol. ii. In some of these crystals the structure was tesselated, as in fig. 158, where ABED, CBEF, are the two external tesselæ, at one of the obtuse angles of the rhomboidal section. If we suppose

Fig. 158.



that these tesselæ are divided into *four* laminæ, 1, 2, 3, 4, and that MN is the principal section, or one of the neutral axes of the central portion of the crystal contiguous to DEF, then the laminæ 1, 1 have their principal section in the direction *aa'*, forming a very small angle with MN; the laminæ 2, 2 have their principal section in the line *bb*, and so on to the superficial laminæ 4, 4, which have their principal section in the direction *dd'*, inclined from 10° ± to 22° ± to MN, the inclination varying in different crystals. The lines *aa'*, *bb'*, &c. are also the principal sections of the corresponding laminæ on the side NC. In like manner, the principal sections *αα'*, *ββ'*, &c. of the laminæ in BCFE, are the principal sections of the corresponding laminæ on the other side AN. As the laminæ, however, are infinite in number, the principal sections have every possible direction between *dd'* and *δδ'*.

Sulph… of pot…

The *bipyramidal sulphate of potash*, which Count Bournon supposed to be a simple crystal, was found by Sir David Brewster to be a tesselated crystal, composed of three pair of crystals of the prismatic sulphate of potash combined so that each pair had their principal axis parallel. When exposed to polarised light, each pair gave the system of biaxal rings, and when held at a distance from the eye, had the tesselated appearance shown in fig. 59, Plate CCCLXXXIV., each opposite pair of the triangles having the same tint.[1]

Apoph… lite.

The most remarkable of this class of minerals, and indeed the most remarkable body in the whole mineral kingdom, is the *tesselated apophyllite*. It crystallizes most commonly in four-sided rectangular prisms, like CD, fig. 60. If we remove the uppermost slice A and the undermost B to the thickness of between the 50th and the 100th of an inch, and examine it either by the microscope or by polarised light, we shall find that it is like other uniaxal plates, giving a single system of rays having the very peculiar colours which have been already described. A number of veins appear at the edges, as shown in the figure. All the other slices lying below this exhibit the beautiful tesselated figure shown in fig. 61. The outer case MNOP, which, as it were, binds together the internal portions, consists of a great number of parallel veins or plates, which give the colours of grooved surfaces. This frame encloses *nine* different crystals, namely, the central lozenge *abcd*, the *four* prisms A, B, C, D with trapezoidal bases, and the *four* triangular prisms *ehl, lmn, nkg, gfe*, all of which are separated by distinct lines or veins, which are nearly all visible by the microscope by a proper method of illumination. In polarised light they are all seen with great facility.

The most extraordinary fact connected with this structure is, *that the central lozenge has only* ONE *axis of double refraction, like the terminal plates A, B, fig.* 60, *while the four prisms A, B, C, D, and the four triangular spaces, have* TWO *axes.* In A and D the planes of the resultant axes are coincident, as in the opposite triangles of sulphate of potash, and lie in the direction MN, while the planes of the resultant axes in B and C lie in the direction OP.

When the plate MONP is exposed to polarised light and turned round its axis before the analysing plate, the lozenge *abcd* will be dark in every position of the plate, while the portions A, B, C, D will depolarise the light, or be luminous, when MO or ON are parallel or perpendicular to the plane of primitive polarisation.

Remarkable as is the structure which we have now described, it is greatly excelled in beauty by another variety of Faroe apophyllite, in which Sir David Brewster discovered the most extraordinary organization. He has given an enlarged coloured drawing of the fine symmetrical tints which it exhibits in polarised light, in the Edinburgh Transactions; but we hope its structure may be understood by the following description which he has given of it. The crystals have a greenish-white tinge, and are aggregated together in masses. The quadrangular prisms are in general below one twelfth of an inch in width; they are always unpolished on their terminal planes; they have the angles at the summit more deeply truncated than the other quadrangular prisms from Faroe; they are always perfectly transparent; and may sometimes be detached in a complete state, with both their terminal summits.

"In examining this variety of apophyllite, I was enabled, by the perfection of the crystals, to study their structure through the natural planes, and at right angles to their axes. The phenomena which this investigation presented to me were of a very singular and unexpected nature. In symmetry of form and splendour of colouring they far surpassed any of the optical arrangements that I had seen, while they developed a singular complexity of structure, and indicated the existence of new laws of mineral organization.

"When a complete crystal of this variety of apophyllite is exposed to polarised light, with its axes inclined 45° to the plane of primitive polarisation, and is subsequently examined with an analysing prism, it exhibits, through both its pair of parallel planes, the appearance shown in fig. 62. In turning the crystal round the polarised ray, all the tints vanish, re-appear, and reach their maximum at the same time, so that they are not the result of any hemitropism, but arise wholly from a symmetrical combination of elementary crystals possessing different primitive forms and different refractive and polarising powers. The difference in the polarising powers is well shown by the variation of tint; and the difference of refractive power may be observed with equal distinctness by examining the

[1] See Edinburgh Philosophical Journal, vol. i. p. 1.

Polarisation.

crystal with the microscope under favourable circumstances of illumination, when the outlines of the symmetrical forms shown in fig. 62 will be clearly visible.

"In examining the splendid arrangement of tints exhibited in the figure, the perfect symmetry which appears in all its parts is particularly remarkable. The existence of the curvilineal solid in the centre; the gradual diminution in the length of the circumscribing plates, in consequence of which they taper, as it were, from the angles of the central rectangle to the truncated angles at the summits; but, above all, the reproduction of similar tints on each side of the central figure, and at equal distances from it, cannot fail to strike the observer with surprise and admiration.

"The tints exhibited by each crystal vary, of course, according to its thickness; but the range of tint in the same plate, and at the same thickness, generally amounts in the largest crystals to three of the orders of colours in Newton's scale. The central portion, and the two squares above and below it, have in general the same intensity, while the four segments round the central portion, and some of the parts beyond each of the squares, are also isochromatic. In the central part the colours have a decided termination; but towards the summit of the prism their outline is less regular, and less distinctly marked; though this irregularity has also its counterpart at the other termination. A part of these irregularities is sometimes owing to the longitudinal striæ on the natural faces of the crystal, so that by carefully grinding these off, the beauty and regularity of the figure is greatly improved.

"In order to ascertain the order of the colours polarised by the crystal, and observe in what manner they passed into one another, I transmitted the polarised light in a direction parallel to one of the diagonals of the quadrangular prism, and thus obtained, as it were, a section of the different orders of colours from the zero of their scale. The result of this experiment, which is shown in fig. 63, was highly interesting, as it displayed to the eye not only the law according to which the intensity of the polarising forces varied in different parts of the crystal, but also the variation in the nature of the tints, and the connection between these two classes of phenomena. At the points in the diagonal *mn*, opposite to *ba* of the crystal, the tints rose to the *seventh* order of colours; and in other two places opposite to *cd*, they were only to the *sixth;* while near the summits at *mn*, they descended so low as the *fourth* order. Hence it follows that the four curvilineal segments, fig. 62, are next to these in intensity; that the central portions of the squares are again inferior to these; and that the weakest polarising force is near the summit of the prisms. At *ab*, the *fourth*, *fifth*, and *sixth* fringes have a singularly serrated outline, exhibiting, in a very interesting manner, the sudden variations which take place in the polarising forces of the successive laminæ.

"Having thus described the structure and properties of the tesselated apophyllite, it becomes interesting to inquire how far such a combination of structures is compatible with the admitted laws of crystallography. The growth of a crystal, in virtue of the aggregation of minute particles endowed with polarity, and possessing certain primitive forms, is easily comprehended, whether we suppose the particles to exist in a state of igneous fluidity or aqueous solution. But it is a necessary consequence of this process, that the same law presides at the formation of every part of it, and that the crystal is homogeneous throughout, possessing the same mechanical and physical properties in all parallel directions.

"The tesselated apophyllite, however, could not have been formed by this process. It resembles more a work of art, in which the artist has varied, not only the materials, but the laws of their combination.

"A foundation appears to be first laid by means of an uniform homogeneous plate, the primitive form of which is pyramidal. A central pillar, whose section is a rectangular lozenge, then rises perpendicularly from the base, and consists of similar particles. Round this pillar are placed new materials, in the form of four trapezoidal solids, the primitive form of whose particles is prismatic; and in these solids the lines of similar properties are at right angles to each other. The crystal is then made quadrangular by the application of four triangular prisms of unusual acuteness. The *nine solids* arranged in this symmetrical manner, and joined by transparent veins performing the functions of cement, are then surrounded by a wall composed of numerous films, deposited in succession, and the whole of this singular assemblage is finally roofed in by a plate exactly similar to that which formed its foundation.

"The second variety of the tesselated apophyllite is still more complicated. Possessing the different combinations of the one which has just been described, it displays, in the direction of the length of the prism, an organization of the most singular kind. Forms unknown in crystallography occupy its central portion; and on each side of it particles of similar properties take their place at similar distances, now forming a zone of uniform polarising force, now another increasing to a maximum, and now a third descending in the scale by regular gradations. The boundaries of these corresponding though distant zones are marked with the greatest precision, and all their parts as nicely adjusted as if some skilful workman had selected the materials, measured the spaces they were to occupy, and finally combined them into the finest specimen of natural mosaic.

"The irregularities of crystallization which are known by the name of *macle* or *hemitrope* forms, and those compound groups which arise from the mutual penetration of crystals, are merely accidental deviations from particular laws which govern the crystallizations in which they occur. The aberrations themselves testify the predominance of the laws to which they form exceptions, and they are susceptible of explanation by assuming certain polarities in the integrant molecules. The compound structure of the apophyllite, however, cannot be referred to these capricious formations. It is itself the result of a general law, to which there are no exceptions, and when more deeply studied and better understood, it must ultimately lead to the introduction of some new principle of organization, of which crystallographers have at present no conception.

"The difficulty of accounting for the formation of apophyllite is in no way diminished by giving the utmost license to speculation. We cannot even avail ourselves of the extravagant supposition of a crystalline embryo, which, like that of animal and vegetable life, gradually expands to maturity. The germ of plants and animals is nourished by a series of organs, of which, however recondite be the operation, we yet see the action and witness the effects; but in the architecture of apophyllite no subsidiary organs are seen. The crystal appears only in its state of perfection; and we are left to admire the skill which presided at its formation, and to profit by the instruction which is so impressively conveyed by such mysterious organization."[1]

We have represented in figs. 66 and 67 the figure produced by polarised light by an internal slice of the barrel or cylindrical apophyllite from Kudlisaet, in Disco Island,

[1] Edinburgh Transactions, vol. ix. p. 323.

brought home by Sir Charles Giésecke. The figures are from different specimens. The *shaded part of them has only one axis of double refraction*, while the *four sectors have two axes*, the luminous sectors being analogous to the prisms A, B, C, D, and the dark figure to the central lozenge *abcd*, in fig. 61. The mechanical structure of the cleavage planes resembles the optical figure even after the planes are ground.[1]

Sect. XV.—*On the Absorption of Light by Uncrystallized Bodies.*

When a beam of light passes through the most transparent media, such as air and water, a certain portion of it *is lost.* This loss of light is particularly apparent in such bodies when a beam of light has traversed a great thickness of the gas or the fluid. This loss of light has been called *absorption*, and the light lost is said to be *absorbed;* a term which we use at present as merely expressing a fact.

There are two kinds of absorption which may be noticed. 1. That in which all the rays of the spectrum are proportionally absorbed or lost; and, 2. that in which different quantities of the differently coloured rays are lost. Those bodies in which the first kind of absorption takes place are *colourless*, and those in which the second kind takes place are *coloured.* In black *ink*, for example, the transmitted light of the sun is white. In red ink it is red, more of the most refrangible rays of the spectrum being lost than of the least refrangible ones.

When a beam of the sun's light falls upon a piece of charcoal, the light is almost wholly lost or absorbed. Sir Isaac Newton thought that the light was reflected or refracted "to and fro" within such bodies till it was lost; but still the question meets us, why is it lost? If it is scattered in all directions it must emerge again from the charcoal, and be visible in some way or other. In order to meet this and other difficulties, the light is supposed to be detained within the body, and somehow or other united to its substance.

In the case of red ink and similar bodies Sir Isaac Newton conceived that the *blue* rays which were lost were reflected by the particles of the ink, while the red rays were transmitted, as in the colours of thin plates; but as we cannot by any process see these *blue* rays, we can only say that they are lost, and the cause of their loss is as difficult to be found as in the phenomena of imperfect colourless transparency.

The following are the general phenomena of coloured absorptions in transparent bodies.

1. *Red* transparent solids or fluids absorb, generally speaking, the blue end of the spectrum.
2. *Blue* substances absorb, generally speaking, the red end of the spectrum.
3. *Green* bodies absorb both the blue and the red ends of the spectrum.
4. *Yellow* bodies absorb the *blue* and part of the *green* of the spectrum.

But when we examine more narrowly the action of coloured bodies on the spectrum, we find that a body may derive its peculiar tint from absorbing two, three, four, up to many hundred separate parts of the spectrum, so that the colour of such a body is the combination of all the parts of the spectrum which are not absorbed. We may infer, however, from the general tint of the body, what parts of the spectrum it has chiefly absorbed. *Red nitrous gas*, for example, must have acted most powerfully upon the blue end of the spectrum, as we have already seen that it does.

Polarisation.

Sir John Herschel.

Three theories of absorption have been recently published, namely, by Sir John Herschel, Baron Wrede, and M. Lamé, all of which are founded upon the undulatory theory. Sir John Herschel conceives that light may be lost within bodies by the interference of different parts of a ray, which, after taking two routes of *different lengths*, meet again in a condition to interfere. This hypothesis has been modified by Mr Whewell in the following manner: "If we conceive," says he,[2] "with Sir John Herschel, a medium which will not transmit vibrations except through certain canals, these canals must have a determinate direction, and therefore such a constitution would give different proportions in different directions. But let a medium consist of certain particles regularly distributed, the intervening space being filled by a medium capable of vibration. Let it be supposed, also, that each vibration, on reaching a medium so disposed, proceeds in part directly and in part by the indirect routes which go *round* some of the particles and rejoin the direct course. We have thus combinations of ramifying and uniting paths, which, though very complex in each direction, are the same in different directions, in consequence of the regular distribution of the particles. If the distribution, though regular, have a reference to certain axes, as in many crystals, the phenomena of absorption may be different in different directions with regard to these axes.

"In this way the theory of ramifying canals comes to coincide with the theory of vibrations, of which parts are differently retarded, and thus interfere with each other; a theory which has been suggested by other authors."

Baron Wrede.

Baron Wrede[3] supposes the particles of a transparent body placed regularly at equal distances, with the ether diffused between them. When a ray of light is propagated directly through this medium, a portion of it encounters some of the particles, and is reflected backwards, then forwards again, and emerges along with the direct ray, so that the reflected and direct portions will be in a state to interfere and destroy each other. This theory, which is analogous to Newton's, or rather the very same as Newton's, is liable to the objection we have already urged to every theory in which the light is supposed to be decomposed by interior reflections. Now, Baron Wrede's hypothesis may explain all the phenomena, such as dark bands and dark lines, which are known to be produced by thin plates of various thicknesses, as Dr Young has stated;[4] and it may even explain those bands and absorptions which have been recently discovered in decomposed glass by Sir David Brewster, where the effects are clearly produced by a combination of a great number of thin plates,[5] but where the reflected light is as copious as the transmitted light. But we cannot conceive it at all applicable to the cases of nitrous gas (to which he has attempted to apply it), and to solids and fluids, in which all attempts have failed to discover any of the reflected rays.

M. Lamé.

The hypothesis of M. Lamé, which we have already stated in our history of Optics, is incompatible with the actual phenomena of absorption. In place of the lines and bands depending on the surface of emergence, the system of lines is determined by the action of the first surface of the body, a fact independent of all theory.

Of all the theoretical views which we have mentioned, we consider those given by Sir John Herschel and Mr Whewell as the most consistent with observation. They re-

Polarisation.

lieve us from the difficulty of accounting for the reflected light; but though they have this in their favour, they are not founded on any direct data, and indeed were brought forward, as Mr Whewell remarks, "to show that there is no incongruity between the undulatory theory and the phenomena of absorption."

Recent inquiries.

An attempt has been recently made by Sir David Brewster to deduce an explanation of absorption, both in uncrystallized and doubly refracting bodies, from direct experiment; but as the details have not been published, we can only at present give a very general notice of it. Having been led to suppose, along with Dr Young,[1] that a transparent medium transmits light in two separate portions, one passing through its ultimate particles, and the other through its pores, and that these portions reunite continually after each successive separation, Sir David Brewster endeavoured so to combine a number of thin plates, that the light transmitted through the whole should move with different velocities, the differences being so small as to produce interference. This task he found to be a very difficult one, but he succeeded, after many failures, in finding a doubly-refracting mineral upon which he could impress this mechanical condition.[2] When he placed a small aperture upon this crystal, in order to exclude as much as possible all the light which had not experienced any change in its velocity, and looked through it at a well-formed prismatic spectrum, or, what was the same thing, analysed the light transmitted by the plate with a good prism, he was astonished at the sight which was presented to him, not only because it confirmed his views on a subject of such high scientific interest, but from the splendour of the phenomena which it displayed. The spectrum was covered with the sharpest bright and dark lines and bands grouped with all the irregularity of the solar and nitrous gas lines. The bright lines of maximum intensity were variously placed; and in almost every spectrum thus formed there was a narrow band of *pure homogeneous* WHITE *light, incapable of being decomposed by prismatic analysis.* But the interest of this result did not stop here. The spectrum of the *ordinary* differed from that of the *extraordinary* ray, and the brightest lines had a different locality in each of them. Here then we have the phenomenon of dichroism, of the absorption of light in crystallized and uncrystallized bodies, and of bright and dark lines and bands in the spectrum, and of the unequal absorption of rays of the same refrangibility, but differing in colour, all displayed by an artificially produced combination, in which we know that the phenomena are owing to the interference of rays differently retarded. It can therefore scarcely be doubted that the varied phenomena of absorption arise from the differences of velocity in the rays which pass through the ultimate particles and through the pores of bodies. The constitution of the body, or the arrangement of the ultimate particles in the first film on which the light is incident, determines the nature of the absorptive action which the body exercises at different thicknesses.

SECT. XVI.—*On Dichroism, and the Absorption of Common and Polarised Light by Doubly Refracting Crystals.*

The name of *dichroism* or *double colours*, was given very appropriately, by M. Cordier, we believe, to a mineral called *iolite*, which in *common light* exhibited two different colours in different directions. Dr Wollaston and several mineralogists had observed this double colour in certain crystals of palladium, tourmaline, and other crystals. The origin of this singular property was not known till Sir David Brewter investigated its origin in *iolite*, and showed that it was connected with the doubly-refracting structure; that it never occurred in the *tessular* crystals which did not possess double refraction.

The connection of dichroism with double refraction, and its general laws, will be understood from the following observations. In a specimen of *yellow Iceland spar* the *extraordinary* image is of an *orange-yellow* colour, while the *ordinary* image is *yellowish-white.* Along the axis of double refraction the colour of the two pencils is exactly the same, and the difference of colour increases with the inclination of the refracted ray to the axis. Hence the difference of colour increases in proportion to the difference of the velocities of the two rays, and is consequently a maximum in the equator of double refraction, and is the same in all parallels; the colour along the axis being the natural colour of the mineral. This is the invariable law of the phenomena in uniaxal crystals. The following are the observations made by the author already referred to.

Colours of the two Images in Crystals with one Axis.

Names of Crystals.	Colour when its Axis is in the Plane of Primitive Polarisation.	Colour when its Axis is Perpendicular at that Plane.
Zircon	Brownish white	A deeper brown
Sapphire	Yellowish green	Blue
Ruby	Pale yellow	Bright pink
Emerald	Yellowish green	Bluish green
Emerald	Bluish green	Yellowish green
Beryl blue	Bluish white	Blue
Beryl green	Whitish	Bluish green
Beryl yellow green	Pale yellow	Pale green
Rock crystal, almost transparent	Whitish	Faint brown
Rock crystal, yellow	Yellowish white	Yellow
Amethyst	Blue	Pink
Amethyst	Grayish white	Ruby red
Amethyst	Reddish yellow	Ruby red
Tourmaline	Greenish white	Bluish green
Rubellite	Reddish white	Faint red
Idocrase	Yellow	Green
Mellite	Yellow	Bluish white
Phos. of lime (lilac)	Bluish	Reddish
———(olive)	Bluish green	Yellowish green
Phos. of lead	Bright green	Orange yellow
Calcareous spar	Orange yellow	Yellowish white
Octohedrite	Whitish brown	Yellowish brown

Sir John Herschel has found this property beautifully displayed in the sub-oxysulphate of iron, which crystallizes in six-sided prisms. Along the axis the colour is a *deep blood-red*, while through the sides of the prism it is of a *light green* colour. Several tourmalines have also been observed by Sir John to have these same colours along the axis, and at right angles to it. There can be little doubt that this property will be found in every crystal of sufficient thickness that has the property of double refraction. Even if the crystal is colourless, a slight inequality in the intensity of the two images may be observed; and when it is distinctly coloured, the difference of intensity is very easily seen, even when the two colours are not of a different kind.

The phenomena of *dichroism* are best seen in crystals with *two* axes of double refraction, and are well exempli-

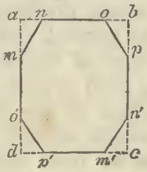
[1] Dr Young made this supposition, not to explain absorption, but to account for the dispersion of colours by refraction. Elem. Nat. Phil. vol. ii. p. 937.

[2] The same property was afterwards found in several crystallized minerals.

fied in *iolite*, a mineral which crystallizes in six or twelve sided prisms. These prisms are of a *deep blue* colour when seen along the axis, and of a yellowish brown colour when viewed in a direction perpendicular to the axis.

If *abcd* is a section of the prism of iolite in a plane parallel to the axis of the prism, the transmitted light will be *blue* through the faces *ab* and *dc*, and *yellowish-brown* through *ad*, *bc*, and in every direction perpendicular to the axis of the prism. If we grind down the angles *a*, *c*, *b*, *d*, so as to replace them with faces *m n*, *m' n'*, and *o p*, *o' p'*, inclined 31° 41′ to *a d*, or to the axis of the prism; then, if the plane *abcd* passes through the resultant axes of double refraction, we shall observe, by transmitting polarised light through the crystal in the directions *a c*, *b d*, and subsequently analysing it, a system of rings round each of these axes. The system will exhibit the individual rings very plainly if the crystal is thin; but if it is thick, we shall observe, when the plane *a b c d* is perpendicular to the plane of primitive polarisation, *some branches of blue and white light, diverging in the form of a cross from the centre of the system of rings*, or the poles of no polarisation, as shown at *p* and *p'*, fig. 67, where the shaded branches represent the blue ones. The summits of the blue masses at *p* and *p'* are tipped with purple, and are separated by whitish light in some specimens, and yellowish light in others. The white light becomes more blue from *p* and *p'* to *o*, where it is quite *blue*, and more yellow from *p* and *p'* to *c* and *d*, where it is completely *yellow*. When the plane *a b c d* is in the plane of primitive polarisation, the poles *p*, *p'* are marked by spots of white light, but everywhere else the light is a deep blue.

Fig. 159.



In the plane *c a d b*, fig. 159, the mineral, when we look through it at common light, exhibits no other colour but yellow, mixed with a small quantity of blue polarised in an opposite plane. The *ordinary* image at *c* and *d* is yellowish brown, and the *extraordinary* image faint blue, the former receiving some *blue* rays, and the latter some *yellow* ones from *c*, and at *a* and *b*, where the difference of colour is still well marked. The *yellow* image becomes *fainter* from *a* and *b* to *p* and *p'*, till it changes into *blue*, and the faint *blue* image is strengthened by other blue rays, till the intensity of the two blue images is nearly equal. As the incident ray advances from *c* and *d* to *p* and *p'*, the faint blue image becomes more intense, and the *yellow* one, receiving an accession of *blue* rays, becomes of a *bluish white* colour. The ordinary image is *whitish* from *p* and *p'* to *o*, and the extraordinary a *deep blue;* but the whiteness gradually diminishes towards *o*, where they are both almost equally blue.

The principal axis of double refraction in *iolite* is negative. The most refracted image is *purplish blue*, and the least refracted one *yellowish brown*.

The following table shows the *colours* exhibited by crystals with *two* axes:

Colours of the two Images in Crystals with two Axes.

Names of Crystals.	Axis of Prism in the Plane of Primitive Polarisation.	Axis of Prism perpendicular to the Plane of Primitive Polarisation.
Mica	Blood red	Pale greenish yellow
Acetate of copper	Blue	Greenish yellow
Muriate of copper	Greenish white	Blue
Olivine	Bluish green	Greenish yellow
Sphene	Yellow	Bluish
Nitrate of copper	Bluish white	Blue
Chromate of lead	Orange	Blood red
Staurotide	Brownish red	Yellowish white
Chloride of gold and sodium	Lemon yellow	Deep orange
Chloride of gold and ammonia	Lemon yellow	Deep orange
Chloride of gold and potassium	Lemon yellow	Deep orange
Augite	Blood red	Bright green
Anhydrite	Bright pink	Pale yellow
Axinite	Reddish white	Yellowish white
Diallage	Brownish white	White
Sulphur	Yellow	Deeper yellow
Sulph. of strontites	Blue	Bluish white
——— cobalt	Pink	Brick red
Olivine	Brown	Brownish white

In the last eight crystals of the preceding table the tints are not given in relation to any fixed line.

In *Withamite*, a crystal whose principal axis is negative in relation to the axis of the prism, the dichroism is beautiful, and is exhibited both in common and polarised light. When common light is transmitted through the two parallel faces of the prism, the tint is of a crimson or amethyst colour, with a mixture of straw colour. Upon turning the crystal round, the yellow tint disappears, and the colour becomes a deep crimson-red. On continuing to turn the prism, the colour changes to a straw-yellow, and at the end of half a revolution the crystal resumes its compound tint. In the groups of crystals which have penetrated the quartz, some of them occupy accidentally the position which gives the yellow colour, others that which gives the red colour, and some that which gives the compound tint, so that, without a knowledge of their dichroitic property, the group might have been considered as composed of three different sets of crystals.[1]

The following table contains the characters of the two pencils in crystals, the number of whose axes has not yet been determined.

Phosphate of iron	Fine blue	Bluish white
Actynolite	Green	Greenish white
Precious opal	Yellow	Lighter yellow
Serpentine	Dark green	Lighter green
Asbestos	Greenish	Yellowish
Blue carb. of copper	Violet blue	Greenish blue
Orpiment	Sulphur yellow	Lighter yellow

Sir David Brewster found that the dichroism of several crystals is changed by heat, and that in some cases this property may be communicated to them. In several coloured glasses, too, he found an analogous property, when they had received the doubly-refracting structure either temporarily or permanently.[2]

Sect. XVII.—*On the Action of the Surfaces of Crystallized Bodies upon Common and Polarised Light.*

It was remarked by Malus, that the action of the surface of Iceland spar upon light is independent of the position of its principal section, and that its surface acts like that of any common transparent body.[3] In examining,

[1] Edinburgh Journal of Science, April 1825, vol. ii. p. 219.
[2] See Phil. Trans. 1819, p. 11; or Edin. Philos. Jour. vol. ii. p. 346.
[3] *Théorie de la Double Refraction*, p. 240, 241; and Biot's *Traité de Physique*, tom. iv. p. 339.

however, the superficial action of this mineral, Sir David Brewster discovered, that all its surfaces, without exception, exercise a remarkable action upon light, and that its polarising angle varied in different azimuths, excepting when the surface was perpendicular to the axis.

If A and A″ are the minimum and maximum polarising angles, viz. in azimuth 0°, or in the plane of the principal section, and in azimuth 90°, or perpendicular to that plane, he found that the variation of the polarising angle was represented by the following expression, where A′ is the polarising angle required at the azimuth a:

$$A' = A + \sin.^2 a \, (A'' - A);$$

in a plane perpendicular to the axis, $A'' - A = 0$, and consequently no change takes place in the polarising angle;
in planes inclined 45° 23′ to the axis on the actual faces of the rhomboid, $A - A = 2° \, 18'$; and
in planes coincident with the axis, $A'' - A = 4°$ nearly.

The following were the measures which our author obtained on the natural faces of the rhomb:

	Azimuth.	Polarising Angle.
Azimuth	0°	57° 74′
	50 57′	58 32
	90	59 32
On faces nearly parallel to the axes:		
Azimuth	0°	54 18
	90	58 14

Sir David Brewster also observed that the polarisation was more complete in azimuth 0° than in azimuth 90° on the faces of the rhomb; but more complete in azimuth 90° than in azimuth 0° in faces parallel to the axis.

As these experiments clearly proved that the forces which produced double refraction extended beyond the surface of Iceland spar, our author became desirous of ascertaining if the light polarised by reflection from the spar suffered any change from the same cause. He therefore thought of weakening the force which produces reflection, in order to allow the interior force to show its weaker influence; and he accomplished this by placing oil of cassia on its surface, and examining the light reflected at the separating surface of the spar and the oil. The experiments which were thus made, and which are detailed in the Philosophical Transactions for 1819, completely proved that the interior force polarised common light out of the plane of reflection, and modified the law of intensity, according to which light is reflected at different angles of incidence.

These experiments excited no attention till 1835, when Professor Maccullagh, of Trinity College, Dublin, began to investigate the laws which regulate the reflection and refraction of light at the separating surface of two media. He had anticipated from theory effects the reverse of those deduced from the preceding experiments; and in order to account for the latter, he was obliged to modify his theoretical views, and was thus led to the result, that when a ray is polarised by reflection from a doubly-reflecting surface, the plane of polarisation deviates from the plane of incidence, except when the axis lies in the latter plane. The formula which expresses this deviation represents very accurately the measures of the polarising angles in different azimuths in the natural faces of the rhomb, the only surface in which the exception is true; but at all other inclinations of the reflecting planes to the axis, the theory and the formula are in fault, for there is a large deviation when the axis or principal section of the crystal is in the plane of reflection.

Professor Maccullagh's success in deducing theoretically the general fact of a deviation increasing as the refractive power of the medium approached to that of the spar, induced Sir David Brewster to resume his inquiries, the general result of which he communicated to the British Association at Bristol in 1836, in the following very brief abstract.

"When light is reflected at the separating surface of two media, the lowermost of which is a doubly-refracting one, the reflected ray is exposed to the action of two forces, one of which is the ordinary reflecting force, and the other a force which emanates from the interior of the doubly refracting crystal. When the first medium is air, or even water, the first of these forces overpowers the second; and, in general, the effects of the one are so masked by the effects of the other, that I was obliged to use oil of cassia, a fluid of high refractive power, in order that the interior force of the calcareous spar which I wished to examine might exhibit its effects independently of those which arise from ordinary reflection. The separating surface, therefore, which I used, had a small refractive power; and the reflecting pencil is so attenuated, especially in using polarised light, that it is almost impossible to use any other light than that of the sun.

"When a pencil of common light is reflected from the separating surface of oil of cassia and calcareous spar, the general action of the spar is to polarise a part of the ray in a plane perpendicular to that of reflection, and thus to produce *by reflection the very same effect that other surfaces do by refraction.*

"On the face of calcareous spar, perpendicular to the axis of the crystal, the effect is exactly the same in all azimuths; but in every other face the effect varies in different azimuths, and depends upon the inclination of the face to the axis of double refraction. On the natural face of the rhomb common light is polarised *in the plane* of reflection, in 0° of azimuth, or in the plane of the principal section; but at 38° of azimuth, the whole pencil is polarised at right angles to the plane of reflection; and in other azimuths the effect is nearly the same as I have stated in my printed paper.

"In order, however, to observe the change which is actually produced upon light, it is necessary to use two pencils, one polarised + 45°, and the other — 45°, to the plane of incidence. The planes of polarisation of these pencils are inclined 90° to each other, and the invariable effect of the *new* force is to augment that angle in the same manner as is done by a refracting surface, while the tendency of the ordinary reflective force is to diminish the same angle. Hence I was led to make an experiment in which these opposite forces might compensate one another. I mixed oil of olives and oil of cassia, till I obtained a compound of such a refractive power that its action in bringing together the planes of polarisation should be equal to the action of the new force in separating them. Upon reflecting the compound pencil from this surface, I was delighted to find that the inclination of the planes was still 90°, and I thus obtained the extraordinary result of a reflecting surface which possessed no action whatever upon common or upon polarised light.

"The action of the new force when the plane of reflection coincides with the principal section of the crystal is obviously inexplicable by any theory of light, though I have no doubt that the undulatory theory may ultimately accommodate itself to this as well as to other classes of phenomena which it does not at present embrace. The difficulty, however, is increased by another result of my experiments, which it is important to notice. On the faces of the spar which are inclined 0°, 45°, 90°, to the axis of double refraction, the action of the new force is symmetrical upon the two pencils of polarised light whose planes are inclined + 45° and — 45° to the plane of incidence; whereas in all intermediate faces, whose inclination to the axes is $22\frac{1}{2}°$ and $67\frac{1}{2}°$, the plane of one of the polarised rays remains stationary, while that of the other is turned round 15°.

"This effect is undoubtedly a very extraordinary one, and indicates some singular structure in calcareous spar, the nature of which it is not easy to conjecture.

"I have examined these phenomena by using, in place of oil of cassia, various fluids whose refractive powers descend gradually to that of water; but it would be a waste of time to give any detailed account of them at present. I shall only state, that the action of the new force becomes weaker and weaker as the force of ordinary reflection is increased, by diminishing the refractive power of the oil which is placed in contact with the spar. With an oil of the highest refractive index, the action of the new force predominates over the feeble power of the ordinary force of reflection. With an oil of a lower index the two forces exactly balance each other; while with oils of still lower indices of refraction, the ordinary force overcomes and conceals the action of the new one.

"Although I have obtained pretty accurate measures of the amount of the deviations produced by the new force, on eight surfaces, differently inclined to the axis, and in various azimuths on these surfaces, yet many experiments are still necessary before we can hope to discover the physical law of the phenomena; and if this should be done, I have no doubt that Mr Maccullagh will be equally successful in the higher attempt of accounting for them by some modification of the undulatory theory."

Sect. XVIII.—*On the Mutual Action of Polarised Rays.*

This curious subject has, we believe, not been studied by any other philosophers but M. Arago and M. Fresnel, and we shall therefore make no apology for giving an account of the results which they obtained, in the words of M. Fresnel himself:[1]—

"In studying the interferences of polarised rays, M. Arago and I found that they no longer exercise any influence upon one another when their planes of polarisation are perpendicular to each other; that is, that they cannot then produce fringes, although all the necessary conditions for their appearance in ordinary cases be scrupulously fulfilled. I shall describe the three principal experiments which illustrate this fact, beginning with that which belongs to M. Arago. It consists in making two pencils, emanating from the same luminous point, and introduced by two parallel slits, traverse two piles of very thin transparent plates, such as those of mica or blown-glass, which are sufficiently inclined to each other to polarise almost completely each of the two pencils, taking care that the two planes are perpendicularly inclined to each other. In this case no fringes can be perceived, whatever care may have been taken thus to compensate the differences of both in varying very gently the inclination of one of the piles; but when the planes of incidence of the piles are no longer perpendicular to each other, they always cause the fringes to appear. In proportion as the planes cease to be parallel, the fringes become weaker, and they disappear altogether when they are rectangular, provided the polarisation of the two pencils has been sufficiently complete. It results from these experiments, that rays polarised in the same plane influence one another, like the rays of light not modified; but this influence diminishes in proportion as the planes of polarisation deviate from one another, and becomes nothing when they are rectangular.

The following is another experiment which leads to the same results. Take a plate of sulphate of lime or of rock-crystal parallel to its axis, and of a uniform thickness; cut it in two, and place each of the halves upon one of the slits of the screen. I suppose that we have turned the two halves in such a way that the edges which were in contact before the division of the plate are parallel, and the axes will also be parallel. But, in this case, we only perceive a single group of fringes in the middle of the bright space as it was before the division of the plates. But, if we turn one of these halves in its plane, thus disturbing the parallelism of their axes, we make two other groups of fainter fringes spring up, situated one on the right, and the other on the left of the group in the middle, and which are completely separated from it, in the white light when the plates of rock-crystal or of sulphate of lime which are used, are only a millimetre thick. It is to be remarked, that the number and breadth of the fringes lying between the middle of one of these groups and the central group, is proportional to the thickness of the plates for crystals of the same kind, or whose double refraction is of the same strength, like rock-crystal and sulphate of lime. In proportion as the angle of the two axes increases, these new groups of fringes become more and more distinct, and attain at last their maximum intensity when the axes of the two plates are perpendicular to each other. In this position, the central group, which had been gradually weakened, altogether disappeared, and is replaced by a uniform light. From this we may conclude, that the rays which produce them, by their interference, are no longer capable of influencing one another.

From the position of these fringes, it is easy to see that they result from the interference of the rays, which have undergone the same kind of refraction in the two plates, since, having travelled with equal velocities, they ought to arrive simultaneously at the middle of the bright space which corresponds to the equal routes, if as we suppose the two plates have the same thickness, and always continue perpendicular to the rays. Hence, the fringes of the central groups were formed by the superposition of those which arise—1. From the interference of the *ordinary* rays of the *left* plate with the *ordinary* ray of the *right* plate; 2. From the interference of the *extraordinary* rays of the *first* plate with the *extraordinary* rays of the *second*. The two eccentric groups, on the contrary, arise from the interference of the rays which have undergone different refractions in the two plates; and as it is the *ordinary* rays which move with the greatest velocity in *sulphate of lime* or *rock-crystal*, we see that, if we employ one of these two species of crystals, the *left* group ought to be formed by the union of the *extraordinary* rays of the *left* plate with the *ordinary* rays of the *right* plate, and the *right* group by the union of the *extraordinary* rays of the *right* plate with the *ordinary* rays of the *left* plate. This being established, it remains now to determine the direction of polarization in each of the pencils which interfere, in order that we may deduce from it what are the relative directions of the planes of polarization which favour or hinder their mutual influence. Analogy shews that the mode of the polarization of light ought to be the same as in the small plates in crystals thick enough to divide it into two distinct pencils. But as this hypothesis might perhaps be an object of discussion, and contradict an ingenious theory of one of our most celebrated philosophers, we shall not present it at first as a certain principle, and we shall have recourse to a direct experiment to determine the planes of polarisation, both of the ordinary and extraordinary rays which emerge from these plates, which we suppose to be one or two millimetres thick. This thickness is sufficient to allow us to cut one of their edges obliquely, and obtain by this prismatic form the separation of the ordinary and extraordinary rays. We then find that they are effectually polarised, the first in the principal section, and the others in a perpendicular direction. If we are not sufficiently convinced that this is their manner of polarisation in emerg-

Polarisation.

[1] We have not seen the original Memoir, but have translated this portion of it from M. Pouillet's very valuable work, entitled *Elemens de Physique Experimental et de Meteorologie*, liv. viii. chap. iii.

Polarisation.

ing from each plate when these two surfaces are parallel, we shall find a new demonstration of this in the facts that we are about to describe, setting out from the principles established by the experiments of M. Arago, and which are besides confirmed by others, of which we are going to speak. If, on the contrary, we no longer question the direction of the polarisation of the ordinary and extraordinary rays, actual experiment will afford us a second demonstration of these principles. When the axes, indeed, of the two plates were parallel, the rays which had experienced the same refractions in the two crystals were found polarised in the same direction, and those of contrary colours in rectangular directions. It is thus that the group of fringes in the middle which proceed from the interference of rays of the same name, had a maximum intensity, and the two others, which resulted from the interference of the rays of contrary names, did not appear again. But when the axes of the two plates formed an oblique angle, of 45° for instance, the rays of a contrary name, and those of the same name, could act at the same time one upon the other, since their polarising planes were no longer rectangular, and the three groups of fringes were produced. When, in short, the axes became perpendicular to one another, the rays of the same colour were polarised in rectangular directions, and the central group, to which it had given birth, vanished, while the *ordinary* rays of the *left* plate were then polarised *parallel* to the *extraordinary* rays of the *right* plate, and this is the cause why the right group which they produce attained its maximum intensity. It is the same with the *left* group, arising from the interference of the *ordinary* rays of the *right* plate with the *extraordinary* rays of the *left* plate.

The following is a *third* experiment, which entirely confirms the results which we have drawn from the first. Having polished a rhomb of calcareous spar upon two opposite faces, wrought with care so as to be quite parallel, I sawed it perpendicularly to these faces, and I obtained in this manner two rhombs of equal thickness, and in which the routes of the ordinary and extraordinary rays were exactly parallel at the same incidence. I placed them one before the other, so that the rays proceeding from the luminous point which had traversed the first rhomb passed through the second, taking care that their faces were perpendicular to the direction of the incident rays; moreover, the principal section of the second rhomb was perpendicular to that of the first, in such a manner that the four pencils which they produced were in general reduced to two; the ordinary pencil of the first rhomb was refracted extraordinarily in the second, and the extraordinary pencil of the first was refracted ordinarily in the second. From this arrangement it followed, that the difference of the route, proceeding from the difference of velocity of the ordinary and extraordinary rays, was found compensated for by the two emerging pencils. They crossed each other, too, at a very small angle, and such that the fringes ought to have had a magnitude much more than sufficient to be seen; and, notwithstanding, though the necessary conditions for the production of the fringes, in ordinary circumstances, were carefully observed, I never could succeed in making them appear.

While I was searching for them with care, holding a magnifying-glass to my eye, I gently varied the direction of one of the rhombs, sometimes to the right, sometimes to the left, in order to compensate the effect resulting from any difference of thickness that might have existed; but in spite of this trial, repeated a great many times, I never could perceive any fringes; and this is not surprising, after what the other experiments have taught us, since the two pencils emerged polarised at right angles to each other. But what proves that the absence of fringes does not depend upon the difficulty of arriving by trials at an exact compensation is, that I easily succeeded in making them appear by employing the light which had been polarised before it entered the rhombs, and in causing it to receive a new polarisation after its emergence. It is, then, completely demonstrable from the experiments which I have described, *that rays polarised at right angles cannot exert any sensible influence upon one another;* or in other words, that their union always produced the same intensity of light, whatever may be the difference of route of the two pencils which interfere.

Another remarkable fact is, that when they have been once polarised in rectangular directions, it is not sufficient that they are brought back to a common plane of polarization, in order that they may give apparent signs of their mutual influence. If in the experiment of M. Arago, indeed, or that which I have described, we cause the rays which have emerged from the two slits, and which are polarized at right angles, to pass through a pile of inclined plates of plane glass, no fringes were perceived, in whatever direction its ray of incidence was turned. Instead of a pile, we may employ a rhomb of calcareous spar, if we incline its principal section at 45° to the plane of polarisation of the incident pencils, so that it divides into two equal parts the angle which they make with each other, each image will contain the half of each pencil, and these two halves having the same plane of polarisation in the same image, ought to produce fringes there, if it is sufficient to bring back the rays to a plane of common polarisation, to re-establish the apparent effects of their mutual influence. But the fringes can never be obtained by this method, as long as the rays have not been polarised in the same plane, before they were divided into two pencils polarised at right angles.

When the light has experienced this previous polarisation, on the contrary, the interposition of the rhomb makes the fringes reappear. The most advantageous direction to give the primitive plane of polarisation, is that which divides into two equal parts the angle of the rectangular planes, in which the two pencils are polarised in the second instance, because then the incident light is equally divided between them. Suppose, in order to fix our ideas, that the primitive plane of polarisation is horizontal, it will be necessary that the planes of polarisation impressed upon each of the two pencils, is inclined 45° to the horizontal plane, the one above it and the other below it, in such a manner that they remain perpendicular. We can obtain this rectangular polarisation either with the help of the two little piles employed in the experiment of M. Arago, or with two plates whose axes are rectangular axes, or, finally, with a single crystallized plate: We shall only consider this last case, the two others presenting phenomena precisely similar.

To divide the light into two pencils, which cross under a small angle, and which may thus produce fringes, the apparatus of two mirrors is generally better than the screen pierced by two slits, because it produces more brilliant fringes. It has, besides, the advantage of giving immediately to the two pencils the previous polarisation necessary to our experiment; it is sufficient for this purpose that the two mirrors should be of glass not tinned, and inclined 35° to the incident rays; care must be taken to blacken them behind, to destroy the second reflection. We place near them, in the line of the reflected rays, and perpendicularly to their direction, a plate of sulphate of lime or of rock-crystal parallel to the axis, and one or two millimetres thick, inclining its principal section 45° to the plane of primitive polarisation, which we have supposed horizontal. The apparatus being thus placed, we only see a single group of fringes across the plate as before its interposition, and it occupies the same place. But if we put before the magnifying-glass, a pile of glass plates, inclined in a horizontal or vertical direction, we discover on each side of the central group another group of fringes, which is the more distant as the crystallized plate is thicker. If we replace the pile of plates by a rhomb of calcareous spar, whose principal section is divided horizontally or vertically, we shall see in each of the two images which it produces, the two systems of additional fringes which the interposition of the pile of plates has caused to appear; and it deserves to be remarked, that these two images are complementary to one another; that is to say, that the obscure bands of the one correspond to the brilliant bands of the other.

We see in this experiment a new confirmation of the principles demonstrated by the preceding ones. The rays which have experienced the refractions of opposite names, cannot influence each other, because, in emerging from the same plate in the case we are now considering, they are found polarised in rectangular directions; consequently the groups to the right and the left cannot exist, at least while we have not re-established the mutual influence of those rays by bringing them to a common plane of polarisation; this is what is effected by the interposition of the pile of plates or of the rhomb. The fringes thus produced are the more distinct, as the two pencils of contrary names which concur in their formation are more equal in intensity; and this is the reason why the direction of the principal section of the rhomb, which makes an angle of 45° with the axis of the plate, is the most favourable to the appearance of the fringes. When the principal section of the rhomb is parallel or perpendicular to that of the plate, the rays refracted ordinarily by the plate pass entirely into one image, instead of being divided between the two, and all the extraordinary rays pass into the other image, so that there can be no more interference between them; and the additional groups of fringes disappear, each image presenting only the fringes which resulted from the interference of the rays of the same name, that is to say, those which compose the central group.

These two groups of additional fringes which polarized light exhibited in the first position of the rhomb, afford one of the most exact methods of measuring double refraction and of studying its law. Their eccentric position, indeed, depends on the difference of route of the ordinary and extraordinary rays which emerge from the plate; and we can judge of the number of undulations by which the extraordinary rays of the right pencil remain behind the ordinary rays of the left one, by the number and width of the fringes comprised between the middle of the right group, and that of the central group. We may determine this difference of route still better, by measuring the interval between the middle of the two extreme groups, which is the double of their distance from the middle of the central group. White light is best suited for this kind of observations, because it is brightest, and renders the central band of each group easier to be observed. By comparing the thickness of the plate with the difference of the observed route, we may deduce from it the ratio of the velocities of the ordinary and extraordinary rays."

Sect. XIX.— *On the Production of Double Refraction by Heat, Cold, Pressure, and slow and rapid Induration.*

The various phenomena of double refraction and the system of polarised rings, may be produced either transiently or permanently in glass and other substances, by heat and cold, compression and dilatation, and by slow and gradual induration. The phenomena thus produced in polarised light are exceedingly beautiful, and throw much light on the subject of double refraction.

Art. I. *On the Transient Influence of Heat and Cold.*

The influence of heat and cold may be exhibited in *cylinders, tubes, spheres, cubes,* and *rectangular plates* of *glass,* all the phenomena of which were discovered by Sir David Brewster.

1. *Cylinders of Glass with one axis of double refraction.*

1. *Negative Axis.*— If we take a cylinder of glass, ACBD, fig. 69, from half an inch to an inch in diameter or upwards, about one-half an inch or more in thickness, and transmit heat uniformly from its circumference to its centre, it will exhibit, when placed between the polarising and the analysing plate, and held about eight or ten inches from the eye, the system of uniaxal rings shewn in fig. 69, exactly similar to those in fig. 29; and by turning round the analysing plate, we shall see the complementary set, as in fig. 31, these rings will be seen as if they were in the substance of the glass, and hence, if we cover up any part of the circular surface, we shall cover up a corresponding part of the system of rings. The axis of the system or of double refraction is here fixed in the axis of the cylinder, and does not lie in every direction parallel to that axis, as in regularly crystallized bodies.

The system of rings thus produced is *negative,* like those in *calcareous spar.*

As soon as the heat reaches the axis of the cylinder, the rings become less bright, and they disappear entirely when the heat is uniformly distributed through the glass.

2. *Positive Axis.*—If we heat a similar cylinder of glass uniformly in boiling oil or otherwise, and cool it rapidly at its edges by encircling its margin with a cold and good conducting material, it will exhibit a similar system, which will vanish when the glass is uniformly cold. This system of rings, however, is *positive,* like those of Zircon, and if it is placed above the equal *negative* system, produced as already described, they will destroy each other. If the two systems are not equal, we shall have a system equal to their difference, as in positive and negative uniaxal crystals. In both these systems the tint at any point varies as the square of the distance of that point from the axis, so that if T is the tint at any distance D, the tint t corresponding to any distance d, will be $t = \frac{\mathrm{T}\,\mathrm{D}^2}{d^2}$. If V is the velocity of the ordinary ray, we shall have the velocity of the extraordinary ray $v = \mathrm{V}^2 + a\,d^2$.

If we transmit polarized light through the cylindrical surface of these cylinders, we shall observe the phenomena of biaxal systems exactly the same, as in rectangular plates, fig. 81, the tints being produced by the action of the positive or negative axis of the cylinder acting in opposition to an axis passing through each diameter of the cylinder, drawn perpendicular to any point in the middle line of the cylindrical surface.

2. *Oval Cylinders, with two axes of double refraction.*

If we perform the two experiments above described with oval cylinders, as in fig. 70, we shall have a system of rings with two axes. A new axis is developed perpendicular to the axis of the cylinder, and in the case of the heated cylinder the new axis at O is a positive one, while in the cooled cylinder it is a negative one, the neutral black lines AD, CB separating the two classes of tints, and corresponding to the dark hyperbolic branches in biaxal systems of rings. The figure referred to is that shewn in azimuths inclined 45° to the plane of primitive polarization; but in the azimuths of 0° and 90°, the branches AD, CB resume the form of the rectangular cross.

3. *Cubes and Parallelopipeds of glass with double refraction.*

Cubes of Glass.— When the shape of the glass is that of a cube as in fig. 71, the figure which it produces in azimuth 0° by the two processes of heating and cooling is that shewn in the figure, the tints being negative or positive according as we apply heat or cold. The complementary system is shewn in fig. 72.

Parallelopipeds of Glass.—In a parallelopiped 0.38 of an inch square, and 1.11 long, the *direct* and *complementary* systems at 0° of azimuth are shewn in fig. 73 and 74. The first of these consist of a black cross, surrounded with beautiful fringes of contrary flexure, and four bright green spots of the third order. The coloured spots at the angles of fig. 74 are of a brilliant pink colour, with a spot of blue in the middle of each. When the azimuth is 45°, the direct and complementary systems change into fig. 75 and 76.

4. *Cylindrical Tubes of Glass with two axes of double refraction.*

When the cylinder has the form of a tube, as in fig. 77, the double refraction is singularly distributed by the application of heat or cold either to the outside ABCD of the cylinder, or to its inside *a b c d*, or to both. A black circular fringe *m n o p*, is the central line which separates the outside or positive structure from the internal negative structure, and *vice versa*. The breadth of the internal annulus *a o* is always less than A *o*, that of the external one. They approach to equality as the bore of the cylinder widens, and the negative structure grows very small, as shewn in fig. 78, when the bore diminishes; so that when the bore becomes infinitely small, the system becomes either wholly negative or positive, according as heat or cold has been used. If when fig. 77 is fully developed, we cut a notch EF in the cylinder, we shall have a biaxal system of fringes in which there is a positive structure between two negative ones, or *vice versa*, as shewn in fig. 79.

The diameter *o p*, fig. 77 and 78, is a geometrical mean between the interior and exterior diameters of the tube, that is $op = \sqrt{(\text{AB} \times ab)}$.

5. *Rectangular Plates of Glass, with planes of double refraction.*

If a well annealed parallelopiped of glass EFCD, fig. 80, is submitted to the processes already described, or even if we lay one edge of it CD on a piece of iron almost red hot, and place the whole between the polarizing and analyzing plates, so that if the heated edge CD is inclined 45° to the planes of primitive polarization, and the eye can see the whole surface of the glass, a series of remarkable phenomena will be produced. The moment the heat enters the lower surface at CD, fringes of brilliant colours are seen above CD, and almost at the same instant, before the heat has reached the upper surface EF, or even the central line *a b*, *similar* fringes will appear at EF. Colours, at first faint blue, then white, yellow, orange, red, &c. of the first order spring up at *a b*, and these central colours are separated from those at the edges by two dark lines or planes MN, OP, corresponding to the hyperbolic branches in biaxal crystals, the double refraction between MN and OP being *negative*, in reference to a line perpendicular to the fringes, while it is *positive* without MN and OP. The tints thus developed are those of Newton's scale.

If T is the central tint in the line *a b*, D the distance of either of the lines MN, OP, from *a b*, the tint *t* at any other distance *d*, will be $t = \text{T} - \frac{\text{T}d^2}{\text{D}^2}$, a formula deduced from the opposition of two axes. The term $\frac{\text{T}d^2}{\text{D}^2}$ represents the influence of the principal axis or axes perpendicular to the line *a b* at every point of it; but as the axis in the plane of the plate produces an uniform tint T, whose maximum is in the line *a b*, where the action of the other axis disappears, and as these axes oppose each other by acting rectangularly, they will compensate each other in the lines MN, OP, and the tint at any point must always be equal to the difference of the tints, or to $\text{T} - \frac{\text{T}d^2}{\text{D}^2}$.

The magnitude 2 D, or the distance between MN and OP, is a function of the breadth of the plate or *b*, and 2 D: V = 10 : 16.02 and D = .312 B².

The fringes seen through the thickness of the plates is shewn in fig. 81, and the one seen through the ends in fig. 82.

If we wish to find the tints in reference to the lines MN, OP, let δ, δ' be the distance of any point from these lines, whose distance from *a b* was *d*, then we have $\delta = 1 - d$, $\delta = 1 - d$ and $\delta\delta' = 1 - d^2$, that is the tint at any point varies, as the product of the distances of that point from the planes of the resultant axes MN, OP. If we make $v^2 = \text{V}^2 + \alpha\delta\delta'$, an expression which gives v the velocity of the extraordinary ray, we shall have the extraordinary refraction in such plates.

6. *Spheres and Spheroids of Glass with double Refraction.*

Spheres.—If we place a sphere of glass in a glass-trough of hot oil or otherwise heat it regularly, we shall find that when the heat is passing to the centre of the sphere, it will exhibit a positive uniaxal system of rings like that in fig. 69, in every direction in which we transmit the polarized light; that is, it will have an infinite number of *positive* axes of double refraction.

If a hot *sphere* of glass is immersed in a glass-trough of cold oil, a similar system of rings will be produced in every possible direction; but it will be *negative*.

Spheroids. If we substitute *oblate* and *prolate* spheroids in place of the sphere in these experiments, we shall find that they will have each a *positive* system of rings round their axis of revolution. If the polarised light is transmitted through an equatorial diameter, we shall find that there are two axes of double refraction, the black cross opening out when the axis of revolution is inclined 45° to the plane of primitive polarisation.

In the prolate spheroid the black cross opens out in a different plane.

7. *On the Effects produced by combining Plates of Glass under the transient influence of heat and cold.*

If we combine any two plates of the same shape, the resulting system of fringes will be equal to the sum of their systems or effects, if the plates are of the same name, that is, both *positive* or both *negative*, or to the difference of their effects, if they are of different names. When the plates are solids or symmetrical forms, such as cylinders, cubes, or quadrangular plates, no essential variation of figure is produced by the combination; but when the plates are rectangular, very interesting phenomena are exhibited when plates of the same or of different names are crossed rectangularly. Sir David Brewster has given formulæ for calculating the forms of the compound or isochromatic curves, as he calls them, but our space will only permit us to exhibit the effects to the eye.

When equal rectangular plates of *similar names*, that is, both negative or both positive, are crossed, the phenomena of the *intersectional fringes*, as they may be called, are shewn in fig. 83, where the isochromatic curves are *hyperbolas*.

When the plates are of *different names*, the one *positive* and the other *negative*, and of the same breadth, and the same number of fringes, the isochromatic curves are *circles*, as in fig. 84.

When the plates are of *different names*, and of different breadths, but containing the same number of fringes, the isochromatic curves will be *ellipses*, as in fig. 85.

8. *On the effects produced by altering the form of, or subdividing plates of glass under the influence of heat or cold.*

If we alter the shape of any of the plates above described, the form of the isochromatic curves is immediately changed. If we cut any rectangular plate into two by a line passing through its middle, each of the two plates thus produced has the property of the whole plate, though the fringes are less numerous. If a plate ABCD gives the tints shewn in fig. 86, OP and MN being the dark neutral lines; then if we cut it with a diamond at ab, so as to subdivide it into two plates, as in fig. 87, each of the plates EFrs, GHrs, will have the same structure as ABCD, viz. two neutral lines op, mn, and assume positive and negative tints.

Art. II. *On the Permanent Influence of Rapid Cooling.*

In March 1814, Sir David Brewster found that glass melted and suddenly cooled, as in the case of Prince Rupert's drops, possessed a permanently doubly refracting power, and he communicated this fact in a letter to Sir Joseph Banks, dated April 8. 1814; and without knowing that Dr Seebeck had published in December 1814 similar results with cubes of glass, our author had discovered that cubes, cylinders, plates, spheres, and spheroids of glass, exhibiting permanently the phenomena described in the preceding pages, may be formed by bringing them to a red heat, and cooling them rapidly and equally on their edges. A great variety of beautiful optical figures, developed in polarised light, may thus be obtained by cooling the glass on metallic patterns. A very simple effect of this is shewn in fig. 88, where the plate of glass was cooled by resting it at its centre on a cylinder of iron.

Art. III. *On the production of Double Refraction by Compression and Dilatation.*

The effects of compression and dilatation in producing double refraction were discovered by Sir David Brewster, and communicated to the Royal Society in 1815. Our limits will permit us to only give a slight notice of them.

The phenomena both of compression and dilatation or extension may be well seen by bending, merely with the force of the hands, a square rod, or a long and narrow plate of glass, as in fig. 89. When it is held between the polarising and analysing plate, eight or ten inches from the latter, with its edge AB inclined 45° to the plane of primitive polarisation, the whole thickness of the glass will be covered with two series of coloured fringes, like those in the figure separated by a dark neutral line MN, where there is neither compression nor dilatation. The fringes on the convex side are *negative*, being produced by the *extension* of the glass in the direction mA, mB, while those on the concave side are produced by the *compression* of the glass in the directions Cn, Dn. The isochromatic curves marked by similar figures, indicating the orders of the colours, are bent as in the figure.

When a plate of bent glass producing fringes crosses another at right angles, the effect at the intersectional space is shewn in fig. 90, where the tint is supposed only to be the white of the first order.

When a plate of bent glass is crossed with a plate crystallized by heat, the fringes in the intersectional square will be *parabolas*, as shewn in fig. 91, whose vertex will be towards the *convex* side of the bent plate, if the principal axis of the other plate is *positive*, but towards the *concave* side, if that axis is *negative*.

Polarisation.

Art. IV. *On the Double Refraction produced by gradual Induration and difference of Density in soft Solids.*

The phenomena of luminous sectors, separated by a black cross at the central part of the uniaxal system of rings, which Sir David Brewster discovered round cavities in the diamond, in glass, and in various gums, arise from the gradual induration of the mass, combined with the elastic pressure of the air included in the cavities: They are therefore not properly cases of induration alone.

When isinglass is dried in a circular trough, it exhibits, by polarised light, the uniaxal system of rings like glass, in fig. 69.

When it is indurated in the form of a rectangular mass, by the exposure of two sides, fringes are produced parallel to these sides, and biaxal like those in rectangular plates of heated glass.

A sphere of transparent jelly or isinglass, when allowed to indurate gradually, will have an axis of double refraction in every direction, like a sphere of glass heated. In like manner an indurated spheroid will exhibit the biaxal structure of a spheroid of glass.

The most splendid examples, however, of this class of facts are exhibited in the lenses of fishes and animals, as shewn in figs. 92 and 93. The first of these shews the doubly refracting structure of the crystalline lens of a cod, along the axis of vision. The central and the external luminous sectors have a *negative* doubly refracting structure, while the intermediate ones have a *positive* structure.[1]

The figure given by the crystalline lens of a cow is shewn in fig. 93, where there are *four* series of luminous sectors, the central ones being *positive*, the next *negative*, the next *positive*, and the last *negative*.[2]

CHAP. II.—ON CIRCULAR POLARISATION.

1. *Circular Polarisation in Rock-crystal and Amethyst.*

The general phenomena of circular polarisation were discovered by M. Arago in 1811. He found that in plates of rock-crystal, the colours polarised along its axis were different from those which he had studied in plates of other crystallised bodies. When they were analysed by a prism of Iceland spar, he found that the two images had complementary colours in the ordinary tints, but, what was remarkable, they descended in Newton's scale as the prism revolved, so that if the tint of the extraordinary image was *red*, it became in succession *orange*, *yellow*, *green*, and *blue*. Hence he concluded that the differently coloured rays had been polarised in different planes in passing along the axis of the rock-crystal.

M. Biot took up the subject at this point, and investigated it with his usual ingenuity and success. He found that while in *some* crystals of quartz the tints descended in the scale of colours, by turning the analysing prism from *right* to *left*, in *others* they descended in the scale by turning the prism from *left* to *right*. The one he called left-handed quartz, and the other right-handed quartz. He took a plate of quartz, for example, $\frac{1}{25}$th of an inch thick, and having polarised the homogeneous colours of the spectrum, he transmitted them in succession along the axis of this plate, and obtained the following

[1] See *Phil. Trans.*, 1816, p. 311.

[2] See *Phil. Trans.*, 1837, vol. ii.

Circular polarisation

results. When the analysing plate was in 0° of azimuth, the *red* light polarised by the plate was a maximum. When the analysing plate was turned from right to left, the *red* tint gradually diminished, and after a rotation of $17\frac{1}{2}$°, it wholly vanished. With a plate 2-25ths of an inch thick, the *red* tint did not vanish till after a rotation of 35°, and so on, every additional 25th of an inch of rock crystal requiring an additional rotation of $17\frac{1}{2}$ to make the tint vanish. A whole inch of quartz, for example, would require $25 \times 17\frac{1}{2}° = 437\frac{1}{2}°$, or one whole turn, and $77\frac{1}{2}$° more to cause the *red* tint to vanish. It is obvious that twenty-five plates of quartz, 1-25th of an inch thick, would produce the same effect as one inch of it.

When *right-handed* plates, however, are combined with *left-handed* ones, the rotation produced is equal to the difference of their actions; thus a plate of left-handed quartz 1-25th of an inch, combined with a plate 2-25ths of an inch, would produce a rotation of only $17\frac{1}{2}$°. The following table contains the rotations produced upon the other coloured rays of the spectrum, as given by M. Biot:—

Names of the ray.	Arc of rotation for 1-25th of an inch in quartz.
Extreme red,	17°·4964
Limit of red and orange,	20 ·4798
Limit of orange and yellow,	22 ·3138
Limit of yellow and green,	25 ·6752
Limit of green and blue,	30 ·0460
Limit of blue and indigo,	34 ·5717
Limit of indigo and violet,	37 ·6829
Extreme violet,	44 ·0827

M. Biot conceived that this property of quartz belonged to its ultimate molecules, but Sir David Brewster proved that this was not the case, by shewing that heat deprived quartz of the property of circular polarisation; and Sir John Herschel's beautiful discovery, that it was connected with the crystallisation of the mineral, put this result beyond a doubt. He found that those crystals in which the plagiedral faces described by Hauy, went round the crystal from *right to left*, exhibited the optical properties of left-handed crystals, and those crystals in which the plagiedral faces leant round the crystals from *left to right*, had the properties of right-handed crystals. Hence he concluded *that whatever be the cause which determined the direction of rotation, the same law acted in determining the direction of the plagiedral faces.*

When Sir David Brewster discovered the system of rings in quartz, he found the tints of circular polarisation occupying, as might have been expected, the inner circle of the rings as shewn in fig. 94, only small portions of the black cross being visible; but these black portions were larger as the plate became thinner.

Fig. 94.

Amethyst.

In examining the structure and properties of the amethyst, Sir David Brewster found that this singular mineral was actually composed of the two different kinds of quartz, viz., the *right-handed* and the *left-handed*. These two kinds of quartz are arranged in veins, as represented in figs. 95, 96. In fig. 95, the shaded veins which correspond to each alternate face of the pyramid turns the planes of polarisation from *right* to *left*, while all the rest of the crystal turns the same planes from *left* to *right;* and what is very interesting, the black lines where these two structures unite have no action whatever on the planes of polarisation. In some specimens these opposite veins are so very minute, that they destroy each other's action upon the polarised ray, and when this happens, the single system of rings appears with its black cross, and entirely free of any of the tints of circular polarisation. The colouring matter of the amethyst is arranged in a very singular manner in relation to these veins; and the fracture across the veins exhibits a beautiful, and sometimes a regular rippled structure, resembling the engine-turning of a watch, and affords an infallible mineralogical character of the amethyst, whether its colour is *yellow, orange, olive, green, blue*, or perfectly colourless.

Figs. 95, 96

Circular polarisation

Fig.

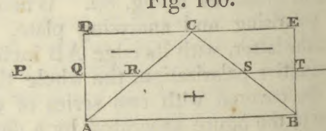
The general structure of well crystallised amethysts is shewn in fig. 96, which is of the natural size, and is taken from one of the finest specimens that Sir David Brewster met with. "On the three alternate sides of the prism," says he, "viz., MN, OP, and QR, are placed sectors M*c*N, O*d*P, Q*a*R, which are divided into two parts by dark lines *cc'*, *dd'*, *aa'*, which separate the direct structures of A, C, and E from the retrograde structures of B, D, and F. On the other three alternate faces of the prisms are placed the three veined sectors M*cba*R, N*cbd*O, and P*dba*Q, which meet at *b* in angles of 120°, and consist of veins of opposite structure, alternating with each other, and so minute, that in many places the circular tints are almost wholly extinguished by their mutual action. The direct sectors A, C, and E, are all connected together by the three radial veins *ba*, *bc*, *bd*, and are therefore to be considered as the expanded terminations of these veins. The retrograde sectors B, D, and F, are expansions of the first retrograde veins next to *bdc*, *dba*, and *abc*, and the lines *cc'*, *dd'*, and *aa'*, are continuations of the dark or neutral lines which separate the first retrograde vein from the direct radial veins.

"All the sectors A, B, C, D, E, and F, are of a *yellowish brown* colour, and all the rest of the crystal is of a *pale lilac* colour, the lilac tints being arranged in the manner previously described. The phenomena which I have now mentioned as existing in this specimen are very common in the amethyst; and I have never yet found a specimen in which the yellow tints were not confined to those portions which formed the expanded terminations of veins; a fact which indicates that this would have been the colour of the crystal, whether its action were direct or retrograde, and that the lilac colour affects in general those portions which are composed of opposite veins."

Fresnel's discoveries.

The subject of circular polarisation received great accessions from the genius of M. Fresnel. He conceived that a ray passing along the axis of quartz should be refracted in two pencils, and he ascertained this to be the case by the following experiment. He took a prism ACB of *right-handed* quartz, having its faces AC, BC, equally inclined to its axis AB, so that a ray PV should be incident at angles of 75° on either face. As a ray, however, refracted at R, would not emerge at all from the other side CB, he took another similar prism, but from a crystal of *left-handed* quartz, and having cut it into two halves, he placed these two halves ACD, BCE, as in the figure, so that he had an achromatic combination of three prisms. Now a ray PQ incident perpendicularly at Q, should pass straight on without deviation, or double refraction, if quartz were like other uniaxal crystals. But if the pencil PQ suffer any double refraction at Q, this double refraction will be doubled at R, because ABC has an opposite kind of double refraction. The same effect takes place at C, so that the ray PQ at its emergence at T, ought to have a very sensible double refraction, even if that at Q was very small. Now M. Fresnel found that this double refraction actually existed, but upon examining the image he found that they had suffered *a new kind of double refraction*, and acquired new properties. In place of their being polarised in opposite planes, like other doubly refracted pencils, which, when examined with a doubly refracting prism, give two unequal images, alternating in brightness during the revolution of the spar prism, they exhibit the following properties:—

Fig. 160.

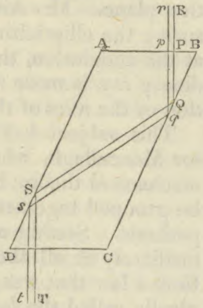


1. Either of the quartz rays, when examined with a spar prism, gave two images of equal intensity in every position

of the prism. Hence they resemble unpolarised light, as if they consisted of two rectangularly polarised rays.

2. They differ from unpolarised light in having the following remarkable and characteristic property. If either of them are incident at right angles, as shewn at RP, fig. 160, upon the face AB of a parallelopiped of crown glass, having its refracting index 1·51, and its angles ABC and ADC $54\frac{1}{2}°$, it will suffer two total reflexions at Q and S, emerging perpendicularly from the surface DC in the direction ST. Now this ray ST is found to be completely polarised in a plane inclined 45° to the plane of its reflexions, whatever may be the position of that plane. If the other ray is incident at *rp*, and is reflected at *q* and *s*, so as to emerge in the direction *st*, the one ray ST will be polarised in a plane 45° to the *right*, and the other *st* 45° to the *left* of the plane of reflexion. Hence they emerge when superimposed in a state of common light. The two rays RP, *rp*, are said to be *circularly polarised*.

Fig. 161.



3. If a ray thus circularly polarised is transmitted through a thin crystallized plate, and parallel to its axis, it is divided by double refraction into two rays of complementary tints, thus shewing a decided difference from a ray of common light; and these complementary colours always differ from those that are produced from light, polarised and analysed in the usual way, by an exact quarter of a tint either in defect or in excess.

4. A circularly polarised ray transmitted again along the axis of rock crystal, and subsequently analysed, produces, like common light, no colours, and differs in this respect from polarised light.

As two circularly polarised rays RP, *rp*, emerge from *Fresnel's rhomb*, (as the parallelopiped of glass ABCD, fig. 160, has been called), in rays ST, *st*, polarised $\pm 45°$ to the plane of reflection, it occurred to Fresnel, and he found it to be so, that a ray TS polarised 45° to the plane of reflexion in the rhomb, would emerge in the direction PR, as a circularly polarised ray, possessing all the properties of one of the rays formed along the axis of quartz.

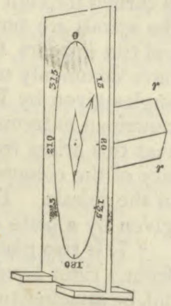
In an extensive series of experiments, of which we shall give some account in the following chapter, Sir David Brewster had occasion to examine some of the kindred phenomena of circular polarisation. His first experiments on this subject preceded those of Fresnel. He found that total reflexion produced polarised tints analogous to those of crystallised laminæ, and he supposed that these colours were produced by the interference of two portions of light, the one partially reflected in the first instance, and the other beginning to be refracted, and caused to return, by the continued operation of the same power.[1] In continuing his experiments, he found that the colours produced by total reflexion did not rise in the scale by successive reflexions; and at the end of 1816, he announced in the *Journal* of the Royal Institution,[2] that he had discovered "a new species of moveable polarisation, in which the complementary tints never rise above the white (the bluish white) of the first order, by the successive application of the polarising influence," &c. He determined experimentally the angles at which this tint was successively produced and destroyed, and thus discovered some of the leading properties of total reflexion. It was Fresnel, however, that discovered this new species of polarisation to be circular, and made those other splendid discoveries which we have just detailed. We owe to Sir David Brewster, however, the discovery of the inversion of the spectrum in the phenomena of total reflexion, of which we shall give some account in the next chapter.

Circular polarisation.

Discovery of Mr. Airy.

In giving the name of circular polarisation to that which is impressed on the two rays along the axis of quartz, M. Fresnel was guided by theoretical considerations. Mr. Airy has, however, taken a different view of the condition of the light forming these two rays in quartz, and has been led to results of very high interest. The following are the experiments, which we shall give in his own words, on which he founded his deductions. They were made with a Fresnel's rhomb, fitted up as in the annexed figure, where the rhomb is shewn at *rr*.

Fig. 162.



"1. If Fresnel's rhomb, mounted as in the annexed figure, be placed to receive the polarised light, so that the plane of reflexion passes through the divisions 45° and 225°, the calc spar will present another appearance 97. The rings are abruptly and absolutely dislocated: those in the upper right hand quadrant and the quadrant opposite to it, are pushed from the centre by one-fourth of an interval, and those in the other quadrants are drawn nearer to the centre by the same quality. The line separating the quadrants is nowhere black; the intensity of its light is uniform, and about equal to the mean intensity. If the plane of incidence pass through 135° and 315°, the phenomena of adjacent quadrants are exactly interchanged. No alteration is made by turning the analysing plate round the incident ray; the lines dividing the quadrants are always parallel and perpendicular to the plane of reflexion at the analysing plate. Fig. 97.

"2. If the plane of reflexion in the rhomb pass through 0° and 180°, or through 90° and 360°, the phenomena are precisely the same, and undergo the same changes as those in ordinary rings. If while the plates are crossed, the rhomb be turned gradually from the position 0° towards 45°, the rings are gradually changed, at first becoming (as far as the eye can judge) elliptical, and then assuming the form represented in fig. 98. Fig. 98.

"3. If a plate of quartz, whether right or left handed, be interposed between the crossed plates, a set of rings is seen like those in fig. 94. As far as the eye can judge, the rings are exactly circular, but there is no black cross, and the central tint is not black, but removed from it by a number of tints in Newton's scale proportional to the thickness of the quartz. Thus with a thickness of 0·48 inch, the central tint is pale pink; with a thickness 0·38 inch, the central tint is bright yellowish green; with thickness 0·26 inch it is a rich red plum colour; with thickness 0·17 inch, it is a rich yellow. Fig. 94.

"The colours then appear to be nearly the same, beginning from the centre, as in Newton's scale, beginning with the tint representing this central tint. At a considerable distance from the centre, four dark brushes begin to be visible, in the same directions as the arms of the black cross in calc spar.

"4. Now, (supposing the crystal right handed), if the plate of quartz be thin, and the analysing plate be turned, the upper part towards the observer's left hand, a bluish short-armed cross appears in the centre, which, on turning further, becomes yellow, and the rings are enlarged. On turning still further, the cross breaks into four dots. The rings are no longer circular, but of a form intermediate between a circle and a square, their diagonals (as well as the cross) being inclined to the left of the parallel, and perpendicular to the plane of reflexion. See fig. 99. If the analysing plate be turned the other way, there is no cross; the form of the rings is changed from circular nearly as in the former case. Fig. 99.

"5. If the plate of quartz be thick, the dilatation, and the rings, and the change of form are all the perceptible phe-

[1] See Chromatics, vol. vi. p. 646, and *Phil. Trans.* 1830, p. 310.

[2] Vol. iii. p. 213.

Circular polarisation

nomena. And on turning the analysing plate continually to the left, the rings continually dilate, and new spots start up continually in the centre, and become rings. If the crystal be left handed, the remarks in this and the last article apply equally well, supposing the analysing plate turned in the opposite direction.

"6. If Fresnel's rhomb be placed in the position 45°, and the light thus circularly polarised pass through the quartz, on applying the analysing plate instead of rings, there are seen two spirals naturally inwrapping each other, as in fig. 100. If the rhomb be placed in position 135°, the figure is turned through a quadrant. If the quartz be left handed, the spirals are turned in the opposite direction. The central tint appears to be white. With the rhomb which I have commonly used, (which is of plate glass, but with the angles given by Fresnel for crown glass), there is at the centre an extremely dilute tint of pink. I think it likely that this arises from the cross in the angles, as the intensity of the colours have no proportion to that in other parts of the spirals. The figure was drawn from the appearances given by a plate of quartz 0·26 inch thick.

Fig. 100.

"7. If two plates of quartz of equal thickness, but cut one from a right handed, and the other from a left handed crystal, be attached together, and put between the polarising and analysing plates, the left handed slice nearest to the polarising plate, the appearance presented is that of fig. 101. Four spirals (proceeding from a black cross in the centre, which is inclined to the plane of reflexion), cut a series of circles at every quadrant. The points of intersection are in the plane of reflexion, and perpendicular to it. This is the simplest way of describing the form; but if we followed the colours which graduate most gently, we should say that the form of each is alternately a spiral and circular arc, quadrant after quadrant.

Fig. 101.

"At a distance from the centre, the black brushes are seen. If the combination be turned, so that the right handed slice is nearest to the polarising plate, the spirals are turned in the opposite direction. This is one of the most beautiful phenomena of optics. The slices from whose appearance the figure was drawn, are each 0·16 inch thick."

The preceding phenomena are described as they appear when examined with an analysing plate of unsilvered glass. The following are the theoretical views which Mr. Airy considers as consonant with these experiments. They had been originally suggested to him by the desire of finding some connecting link between the peculiar double refraction in quartz, and the common double refraction.

"1. I suppose the ordinary rays to consist of light elliptically polarised, the greater axis of the ellipse being perpendicular to the principal plane, and the extraordinary rays to consist of light elliptically polarised, the greater axis of the ellipse being in the principal plane.

"2. I suppose that when the ordinary ray is right-elliptically polarised, the extraordinary ray is left-elliptically-polarised, and *vice versâ*.

"3. I suppose that the proportions of the axes of the two ellipses are the same, each proportion being one of equality when the direction of the ray coincides with the axis, and becoming more unequal, according to some unknown law, as the direction is more inclined to the axis; the minor axes of the ellipses having sensible magnitudes when the rays are inclined 10° to the axis.

"4. I suppose that the course of the rays after refraction can be determined by the construction given by Huygens for calc spar, with this difference only, that the prolate spheroid for determining the course of the extraordinary ray must not be supposed to touch the sphere for determining the course of the ordinary ray, but must be entirely contained within it."

Circular polarisation

In a supplement to his investigations, Mr. Airy remarks, that he has not yet ascertained the law which connects the ellipticity of the rays with the angle that they make with the axis. He considers, however, the following points as made out:—

"One of the rays is certainly right-handed elliptical, and the other certainly left-handed elliptical. The major axis of one is certainly perpendicular to the principal plane of the crystal, and the major axis of the other is certainly in that plane. Mr. Airy remarks, that in some trials for measuring the ellipticities of the rays, he seems to have arrived at the conclusion, that the proportion of the axes of the ordinary ray is more nearly one of equality than the proportion of the axes of the extraordinary ray."

Professor Maccullagh.

This subject has recently been investigated by Professor Maccullagh, whose object was to pave the way for a mechanical theory, by shewing that all the phenomena may be grouped together by means of a simple geometrical hypothesis. Setting out from this hypothesis, he arrives immediately at all the known laws, and obtains at the same time a law that was previously unknown, and which is technically called the *law of ellipticity*. By this law Professor Maccullagh has been able to compute the ellipticities observed by Mr. Airy in rays inclined to the axis of quartz, from the angles of rotation observed by M. Biot in rays parallel to that axis.[1]

The phenomena of circular polarisation were discovered by Sir David Brewster, in plates of glass possessing the doubly refracting structure. M. Dove of Berlin has found it also in compressed glass and has published an interesting memoir on the subject, in which he takes little notice of the previous labours of others, on the various subjects of which he treats. As our limits will not permit us to give any account of its contents, we must refer our readers to the original memoir.[2]

Sect. I.—*On the Circular Polarisation of Fluids.*

Although this remarkable property was discovered in some fluids by M. Seebeck by independent observation, yet M. Biot had anticipated him in it, and has made this subject so completely his own, by a series of the most elaborate and beautiful researches, that if he had done nothing else for science, they would have ensured him a high reputation. We regret extremely that our limits will not permit us to give any thing like a full and satisfactory account of his discoveries, particularly those contained in his valuable paper of 1832. We must therefore refer the reader to his original memoirs, and present to them in as abridged a form as possible his leading results.

M. Biot discovered that some fluids turn the planes of a polarised ray from right to left, and others from left to right. He found also that the tints rose in the scale as in quartz by an increase in the thickness of the fluid. The following table contains some of his results:—

I. *Fluids that turn the Plane of Polarisation from Left to Right.*

	Colours.	Arcs of rotation with the red rays, with a thickness of 200 millimetres.
Oil of fennel seeds	Palish green	26°·32
—— carraway seeds	Colourless	131 ·58
—— lavender	Greenish	4 ·04
—— rosemary		6 ·58
—— marjoram	Orange yellow	23 ·68
—— sassafras	Yellow	7 ·06
—— savine	Yellow	14 ·12
—— bitter oranges	Greenish yellow	157 ·89
—— bergamot	Colourless	38 ·16
—— lemons	Colourless	110 ·53
Neroli, common	Yellow	$\frac{7}{12}$ths of oil of oranges.
—— fine	Orange yellow	Do.
—— superfine	Reddish or.	$\frac{5}{28}$ths of com. Neroli.

[2] This memoir has been translated and published in Taylor's Scientific Memoirs, vol. i. part i. p. 75.

Circular polarisation

II. *Fluids that turn the Plane of Polarisation from Right to Left.*

Essential oil of turpentine	Greenish	59°·21
Naphtha	Greenish	15 ·21
Oil of anise seeds	Greenish	1 ·51
—— mint	Limpid	32 ·28
—— rhue	Yellowish	conjectured.

Oil of mustard and oil of *bitter almonds* exercise no action upon polarised light.

Camphor.

M. Biot found that in a solution of *natural camphor* in alcohol, in which there was 0·37117 of camphor in weight to I of the solution, and its density 0·87221, the rotation for *red* light, and a thickness of 152 millimetres, was 17° ·56 from *left to right.* A solution of *artificial camphor* in alcohol, on the other hand, with 0·0917 of camphor to of the solution, and having its density 0·8455, and in a thickness of 1357 millimetres, produced only a rotation of 24°, but in the opposite direction, from *right to left.* In *gum from Senegal,* of which 47·4 parts was dissolved in 99·1 of distilled water there was a rotation from right to left, of 12° 13′ 20″, with a thickness of 152 millimetres.

The following table contains the results which our author obtained from different kinds of sugar :—

From Left to Right.

	Proportion of sugar in 1 of the solution.	Density.	Arc of rotation of red light in a thickness of 152 millimeters.	Molecular power of rotation.
Sugar of canes, syrup of..	0·25	1·1052	23° 28 45	83° 94
——————	0·50	1·2311	52 7 30	
——————	0·65	1·3114	70 11 15	
Sugar of milk	0·14	1·0537	10 21 40	70·18
——Starch	0·65	1·2460	48 30 0	59·99
Crystallisable principle of honey	0·34	1·1329	16 47 30	43·32
Sugar of grapes				59·10

From right to left.

The rotation being observed for the yellow rays, and the thickness of solution 152 millimeters as before.

Sugar of grapes in syrup	10° 0′ 0″
Uncrystallisable principle of honey, alcoholic solution	3 38 20
——————the same dry	11 15 0

M. Biot made experiments with various vegetable juices, all of which gave a slight rotation from *right to left.*

	Thickness of fluid.	Rotation.
Juice of grapes white	160 millimetres	6°
Do. red and white mixed	160 ————	6·25
Chasselas	160 ————	5·50
Muscat	160 ————	5·33
Verjuice	160 ————	1·81
Chasselas of Fountainbleau	160 ————	8·00
Common black grape	160 ————	10·00
Apples for cider	————	3·33
Red gooseberries very ripe	80 ————	1·81
Berries of the service tree	160 ————	2·5

M. Biot also found, that claret, white champagne, alcohol, sulphuric ether, citric acid dissolved in the proportion of 30 to 37 of water, sulphuric acid pure and colourless, and olive oil, produced no effect upon polarised light.

He found, however, that tartaric acid dissolved in the proportion of 53 of acid to 52 of water produced a rotation of 8° *from right to left.*

Dextrine.

One of the most curious discoveries contained in M. Biot's memoir, is that of the powerful rotatory property of *dextrine* an uncrystallisable syrup which is found in the farina of rice, wheat, and even of ligneous tissue.[1] It differs from gum in producing an opposite rotation, and from sugar in its superior power of rotation, which is almost triple of that which is exerted by sugar of canes. It surpasses all animal and vegetable substances at present known, at equal densities and thicknesses, in turning round the plane of a polarised ray,—rock crystal only being superior to it. The name of dextrine has been given to it in order to mark the direction as well as the powerful energy of its force of rotation.

M. Biot and M. Persoz have more recently found a sugar of starch, whose power of rotation is almost equal to that of crystallised sugar of canes. They have also discovered that, when sugar of canes is dissolved in water mixed with dilute sulphuric acid, and heated below the boiling point, it loses its power of turning the planes of polarisation from left to right, like sugar of grapes not solidified. Sugar of starch submitted to the same process did not experience this inversion.

M. Biot likewise found, that the colouration of liquids did not exercise any influence on their rotatory property.

We regret that want of room prevents us from giving any account of M. Biot's more recent, and extremely interesting researches on the growth and nutrition of plants. These researches have a high practical value, and shew in a striking manner that the most abstract researches in physical science will sooner or later find some useful application.

Elliptical polarisation

CHAP. III.—ON ELLIPTICAL POLARISATION.

The phenomena and laws of elliptical polarisation, as they are at present known, have been investigated only by Sir David Brewster. This species of polarisation forms the connecting link between *plane polarisation* and *circular polarisation,* passing nearly into the former when exhibited by *galæna* and into the latter when exhibited by *silver.*

Sir David Brewster found at an early period, what Malus had previously observed, that the light reflected from metals was polarised in different planes. The former, however, found, that the pencil polarised in the plane of reflexion was always more intense than that polarised in a perpendicular plane, and which he conceived had entered the metal and been partially absorbed. He found the difference between the intensities of these pencils to be least in silver and greatest in galæna, metals which had an intermediate effect, being arranged as in the following table.

Order in which the metals polarise most light in the plane of reflexion.

Galæna.	Steel.	Copper.	Fine gold.
Lead.	Zinc.	Tin plate.	Common silver.
Grey cobalt.	Speculum metal.	Brass.	Pure silver.
Arsenical cobalt.	Platinum.	Grain tin.	Total reflexion from glass.
Iron pyrites.	Bismuth.	Jewellers' gold.	
Antimony.	Mercury.		

He found also that, by increasing the number of reflexions, *the whole of the light could be polarised in one plane.* The white light of a wax candle 10 feet distant, is polarised by *eight* reflexions from *steel* between 60° and 80°, whereas it requires more than *thirty-six* from *silver,* and in total reflexion where the elliptical polarisation becomes circular; and when the two pencils are equal, the total polarisation of the pencil cannot be effected by any number of reflexions.

The action of metals upon polarised light presents us with a series of very extraordinary phenomena. One of the first of these which was discovered by our author, was the action of successive reflections from silver and gold upon polarised light. These reflexions are made from two metallic plates placed between the polarising and analysing plate or rhomb, and when the plane of metallic reflexions is parallel or perpendicular to the plane of primitive polarisation, its

[1] Dextrine may be procured from laundry starch by hot or cold acids, by potash, or by hot water, any one of which will rupture the envelope and set free the dextrine.

Elliptical polarisation

azimuth will be 0°, 90°, 180°, &c. and when it is inclined 45° to that plane, its azimuth will be 45°, 135°, &c.

In azimuth 0° no colours are observed by reflexions from two plates of silver placed parallel to one another, just as in the case of crystallised laminæ whose axes are in 0° of azimuth.

At 45°, 135° of azimuth, the most brilliant complementary colours are seen, either by turning round the analysing plate, or by using a rhomb of spar that gives two images. These colours become fainter and fainter while the azimuth changes from 45° to 90°, or from 45° back to 0°, exactly like those of crystallised laminæ.

When a small number of reflexions are used, the tints are fainter and less brilliant, and they increase with the number of reflexions. There is an angle of reflexion about 75°, at which the tints are brightest, and they become fainter as the reflexions are performed at greater or at less angles.

All the other metals in the preceding table, as well as total reflexion from glass, give analogous colours, but they are most brilliant in silver, and diminish towards galæna.

Now, it is obvious, that at about 75° of incidence (if we suppose the metal to be steel) the polarised light which it reflects has acquired some new physical property.

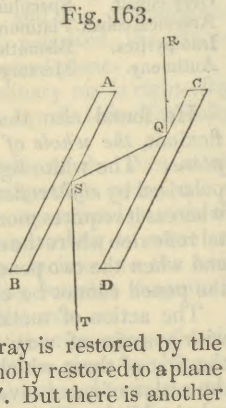
1. It is neither *common light* nor *partially polarised* light, because if we reflect it a second time at 75° *it is restored* to light polarised in one plane.

2. It is not polarised light, because it does not vanish during the revolution of the analysing rhomb.

In order then to discover its nature, let it be transmitted along the axis of Iceland spar. The common uniaxal system of rings is changed into that shewn in fig. 102, which is similar to the effect produced by crossing the uniaxal system of rings with a thin film polarising the pale blue of the first order. If we substitute for the Iceland spar, films of sulphate of lime, we shall find that their tints are increased or diminished according as the metallic action coincides with or opposes that of the crystal. This experiment led our author into the erroneous opinion that metals acted like crystallised plates; but when he found that a second reflexion at 75° destroyed the effect of the first reflexion, he saw that this opinion was untenable, and was led to consider the phenomena as having some resemblance to those of circular polarisation.

We have already seen, that a circularly polarised ray RP, fig. 161, emerges after two total reflexions in the direction ST, polarised 45° to the plane of the two reflexions in every azimuth. Now, if we reflect a ray of light R polarised +45° at Q from one plate of *silver* CD, the rays QS will have acquired a property analogous to that of circular polarisation; for if it is reflected a second time at S, the reflected ray ST will emerge polarised 39° 48′ to the plane of reflexion. Now the difference between this result and that from total reflexion, is that one reflexion from silver impresses the same character upon light, whereas in total reflexion two reflexions are necessary. Another point of difference is, that when the ray is restored by the same number of reflexions, it is not wholly restored to a plane — 45°, but only to a plane — 39° 48′. But there is another difference of a very interesting kind. In circular polarisation, the ray has the same properties on all its sides, and the angles of reflexion at which it is restored to polarised light in different azimuths, are all equal to the radii of a circle described round the rays. "Hence," says our

Fig. 163.



Elliptical polarisation

author, "without any theoretical reference the term *circular polarisation* is from this and other facts experimentally appropriate.[1] In like manner, *without referring to the theoretical existence of elliptical vibrations* produced by the interference of two rectilineal vibrations of unequal amplitudes, we may give to the new phenomenon the name of *elliptic polarisation*, because the angles of reflexion at which this kind of light is restored to polarised light, may be represented by the variable radius of an ellipse."

Now, it is a curious fact, that while silver restores the ray to angles of 39° 48′, other metals restore it to angles deviating more and more from 45°, as is shewn in the following table:

	Inclination of restored ray.		Inclination of restored ray.
Total reflexion from glass	45° 0′	Bismuth	21° 0′
Pure silver	39 48	Speculum metal	21 0
Common silver	36 0	Zinc	19 10
Fine gold	35 0	Steel	17 0
Jewellers' gold	33 0	Iron pyrites	14 0
Grain tin	33 0	Antimony	16 15
Brass	32 0	Arsenical cobalt	13 0
Tin plate	31 0	Cobalt	12 30
Copper	29 0	Lead	11 0
Mercury	26 0	Galæna	2 0
Platina	22 0	Specular iron	0 0

Hence it appears that the elliptic polarisation passes into circular nearly in the case of *silver*, and into plane polarisation in the case of *galæna;* the ellipsis becoming nearly a *circle* in the former case, and a *straight* line in the latter.

As light polarised + 45° suffers different degrees of elliptical polarisation by one reflexion from metals, and is restored again to polarised light, though in different planes, by a second reflexion, so it exhibits the same phenomena at 3, 5, 7, 9 in reflexions, and is restored to polarised light by 4, 6, 8, 10 reflexions at the same angle. The following table shews the inclination of the plane of polarisation of the restored ray to the plane of reflexion, in various numbers of reflexions from silver and steel.

Number of Reflexions.	Inclination of the plane of the polarised ray. Steel.	Silver.
2	— 17° 0′	— 38° 15′
4	+ 5 22	+ 31 52
6	— 1 38	— 26 6
8	+ 0 30	+ 21 7
10	— 0 9	— 16 56
12	+ 0 3	+ 13 30
18	— 0 0	— 6 42
36	0 0	+ 0 47

These results shew in the clearest manner the reason why common light is polarised by 8 reflexions from *steel*, and not till after 36 reflexions from silver, the planes of inclination of the two rectangularly polarised rays requiring in each case that number of reflexions to bring them into a state of parallelism.

The angles at which elliptical polarisation is produced by one reflexion, may be regarded in the present state of our knowledge of the subject as the angle of maximum polarisation, and its tangent as the index of refraction of the metal, as given in the following table:

Name of metal.	Angles of maximum polarisation.	Index of refraction.
Grain tin	78° 30′	4·915
Mercury	78 27	4·893
Galæna	78 10	4·773
Iron pyrites	77 30	4·511
Grey cobalt	76 56	4·309
Speculum metal	76 0	4·011
Antimony melted	75 25	3·844
Steel	75 0	3·732
Bismuth	74 50	3·689
Pure silver	73 0	3.271
Zinc	72 30	3·172
Tin plate hammered	70 50	2·879
Jewellers' gold	70 45	2·864

1 See Sir John Herschel's *Treatise on Light*, § 1050.

Elliptical polarisation.

We may produce elliptical polarisation by a sufficient number of reflexions at any given angle, in the same manner as in plane polarisation. The following table contains the results of observations made with *steel:*

Number of reflexions at which elliptical polarisation is produced.	Number of reflexions at which the pencil is restored to a single plane.	Observed angle of incidence.
3 9 15, &c.	6 12 18, &c.	86° 0′
$2\frac{1}{2}$ $7\frac{1}{2}$ $12\frac{1}{2}$, &c.	5 10 15, &c.	84 0
2 6 10, &c.	4 8 12, &c.	82 20
$1\frac{1}{2}$ $4\frac{1}{2}$ $7\frac{1}{2}$, &c.	3 6 9, &c.	79 0
1 3 5. &c.	2 4 6, &c.	75 0
$1\frac{1}{2}$ $4\frac{1}{2}$ $7\frac{1}{2}$, &c.	3 6 9, &c.	67 40
2 6 10, &c.	4 8 12, &c.	60 20
$2\frac{1}{2}$ $7\frac{1}{2}$ $12\frac{1}{2}$, &c.	5 10 15, &c.	56 25
3 9 15, &c.	6 12 18, &c.	52 20

At an incidence of 67° 40′ elliptical polarisation is produced by $1\frac{1}{2}$, $4\frac{1}{2}$, $7\frac{1}{2}$ reflexions. Hence we draw the interesting conclusion, that the ray must have completed its elliptical polarisation in the middle of the *second* and *fifth* reflexion; that is, when it had reached its greatest depth within the metallic surface. It then begins to resume its state of polarisation in a single plane, and recovers it at the end of the 3d, 5th, and 7th reflexion. Another very interesting effect is produced when one reflexion is made on one side of the polarising angle, and the other reflexion on the other side. A ray that has been partially elliptically polarised by one reflexion at 85° does not as in plane polarisation acquire more by a reflexion at 54°, but it retraces its course, and recovers its state of single polarisation.

We have seen that by *two* reflexions, there is only *one* angle, viz. 73° for silver, at which the elliptically polarised ray can be restored to plane polarisation. At *three* reflexions there are *two* angles, viz. 63° 43′, and 79° 40′, at which the restoration can take place, at *four* reflexions *three* angles, and so on. This phenomena is exhibited to the eye in fig. 103, where the concentric arches I, I; II, II, &c., represent the quadrant of incidence from *one, two*, &c. reflexions, B being the point of 90° and C that of 0°. The point D on the line A is the point or line of maximum elliptic polarisation, viz. 73° for silver, and the figures 1, 2, 3, 4, 5, indicate the points or nodes of restoration, and their distances from C, the corresponding angles of incidence at which the restoration takes place. The loops or double curves lying between the points 1, 2, 3, &c. are drawn to give an idea of the intensity of the elliptic polarisation which has its minimum at 1, 2, 3, &c. and its maximum at the white intermediate parts. These points of maximum intensity do not bisect the loops, or are not equidistant from the minima; but such is their relation that the *maximum* for n reflexions is the minimum for $2n$ reflexions. These phenomena lead us to the explanation and analysis of the complementary colours which accompany elliptical and circular polarisation.

Fig. 103.

On the Colours of Elliptical and Circular Polarisation.

When the preceding experiments are made with homogeneous light, we find that the points and angles of restoration vary for the differently coloured rays. Thus in *silver* we have the maximum polarising angle as follows:

		Corresponding index of refraction.
For red light	$75\frac{1}{2}$	3·866
For yellow light	73	3·271
For blue light	$70\frac{1}{2}$	2·824

Hence it is obvious that at the point of restoration where the *blue* rays are restored, and vanish, the *red* rays are not restored, and consequently will appear when the principal section of the analysing rhomb is in the plane of reflexion. Here, then, we have the cause of the phenomena of the complementary colours seen in reflexion from metals. They are analogous to the colours in *oil of cassia*, and *chromate of lead* at the maximum polarising angle.[1]

Elliptical polarisation

Fig. 103.

But the remarkable result of the preceding measures is, that in *metallic* as well as in *total reflexion*, the *index of refraction is less for blue than for red light*, or in the language of the undulatory theory, the refractive index increases with the length of the wave. In a recent communication to the Royal Irish Academy,[2] on the propagation of light in uncrystallized media, Professor Lloyd has obtained an expression for the velocity of the propagation of light, each of its terms consisting of two parts with opposite signs, one of which is due to the action of the ether and the other to that of the body. Conceiving, therefore, that there may be bodies in which the principal term is nearly nothing, the principal part of the expression will be that derived from the second term; and if that term be taken as an approximate value, it will follow that the refractive index of the substance must be in the subduplicate ratio of the length of the wave nearly. "Now," says Professor Lloyd, "it is remarkable that this law of dispersion, so unlike any thing observed in transparent media, agrees pretty nearly with the results obtained by Sir David Brewster in some of the metals. In all these bodies, the refractive index (inferred from the angle of maximum polarisation) increases with the length of the wave. Its values for the *red, mean*, and *blue*, ray in *silver*, are 3·866, 3·271, 2·824, the ratios of the second and third to the first being .85 and .73. According to the law above given, these ratios should be .88 and .79."

Professor Maccullagh has very recently[3] endeavoured to represent the phenomena described in the preceding pages by empirical formulæ, in the same manner as Fresnel represented those of total reflexion. The following is a brief abstract of Professor Maccullagh's researches, which we shall give in his own words.

"The author observes, that the theory of the action of metals upon light is among the *desiderata* of physical optics, whatever information we possess upon this subject being derived from the experiments of Sir David Brewster. But, in the absence of a real theory, it is important that we should be able to represent the phenomena by means of empirical formulæ; and accordingly, the author has endeavoured to obtain such formulæ by a method analogous to that which Fresnel employed in the case of total reflexion at the surface of a rarer medium, and which, as is well known, depends on a peculiar interpretation of the sign $\sqrt{-1}$. For the case of metallic reflexion, the author assumes that the velocity of propagation in the metal, or the reciprocal of the refractive index, is of the form

$$m\,(\cos.\chi + \sqrt{-1}\,\sin.\chi)\,;$$

without attaching to this form any physical signification, but using it rather as a means of introducing two constants (for there must be two constants, m and χ, for each metal) into Fresnel's formulæ for ordinary reflexion, which contain only one constant, namely, the refractive index.

"Then if i be the angle of incidence on the metal, and i' the angle of refraction, we have

$$\sin.\,i' = m\,(\cos.\chi + \sqrt{-1}\,\sin.\chi)\,\sin.\,i, \qquad (1)$$

and therefore we may put

$$\cos.\,i' = m'\,(\cos.\chi' - \sqrt{-1}\,\sin.\chi')\,\cos.\,i, \qquad (2)$$

if $$m'^4\cos.^4 i = 1 - 2\,m^2\cos.\,2\chi\,\sin.^2 i + m^4\sin.^4 i, \qquad (3)$$

and $$\tan.\,2\chi' = \frac{m^2\sin.\,2\chi\,\sin.^2 i}{1 - m^2\cos.\,2\chi\,\sin.^2 i}. \qquad (4)$$

"Now, first, if the incident light be polarised in the plane

---

[2] Jan. 9, 1837.

[3] Proceedings of Royal Irish Academy, Oct. 24, 1836.

Elliptical polarisation

of reflexion, and if the preceding values of sin. i', cos. i', be substituted in Fresnel's expression

$$\frac{\sin.\ (i-i'}{\sin.\ (i+i')},$$

for the amplitude of the reflected vibration, the result may be reduced to the form

$$a\ (\cos.\ \delta - \sqrt{-1}\ \sin.\ \delta), \tag{5}$$

if we put

$$\tan\psi = \frac{m}{m'}, \tag{6}$$

$$\tan \delta = \tan 2\psi \sin (\chi + \chi') \tag{7}$$

$$a^2 = \frac{1 - \sin 2\psi \cos (\chi + \chi')}{1 + \sin 2\psi \cos (\chi + \chi')}. \tag{8}$$

Then according to the interpretation, before alluded to, of $\sqrt{-1}$, the angle δ will denote the *change of phase*, or the retardation of the reflected light; and a will be the amplitude of the reflected vibration, that of the incident vibration being unity. The values of m', χ', for any angle of incidence, are found by formulæ (3), (4), the quantities m, χ, being given for each metal. The angle χ' is very small, and may in general be neglected.

"Secondly, when the incident light is polarised perpendicularly to the plane of reflexion, the expression

$$\frac{\tan (i - i')}{\tan (i + i)}$$

treated in the same manner, will become

$$a'(\cos \delta' - \sqrt{-1} \sin \delta') \tag{9}$$

if we make

$$\tan \psi' = mm', \tag{10}$$

$$\tan \delta' = \tan 2\psi' \sin (\chi - \chi'), \tag{11}$$

$$a'^2 = \frac{1 - \sin 2\psi' \cos (\chi - \chi')}{1 + \sin 2\psi' \cos (\chi - \chi')}; \tag{12}$$

and here, as before, δ' will be the retardation of the reflected light, and a' the amplitude of its vibration.

"The number $\text{M} = \frac{1}{m}$ may be called the *modulus*, and the angle χ the *characteristic* of the metal. The modulus is something less than the tangent of the angle which Sir David Brewster has called the *maximum polarising angle.* After two reflections at this angle, a ray originally polarised in a plane inclined 45° to that of reflexion, will again be plane polarised in a plane inclined at a certain angle ϕ (which is 17° for steel) to the plane of reflexion; and we must have

$$\tan \phi = \frac{a'^2}{a^2} \tag{13}$$

Also, at the maximum polarising angle we must have

$$\delta' - \delta = 90° \tag{14}$$

And these two conditions will enable us to determine the constants M and χ for any metal, when we know its maximum polarising angle and the value of ϕ; both of which have been found for a great number of metals by Sir David Brewster. The following table is computed for steel, taking $\text{M} = 3\frac{1}{2}$, $\chi = 54°$.

	δ	δ	a^2	a'^2	$\frac{1}{2}(a^2 + a'^2)$
0°	27°	27°	·526	·526	·526
30	23	31	·575	·475	.525
45	19	38	·638	·407	·522
60	13	54	·729	·308	·518
75	7	98	·850	·240	·545
85	2	152	·947	·491	·719
90	0	180	1·	1·	1·

"The most remarkable thing in this table is the last column, which gives the intensity of the light reflected when common light is incident. The intensity *decreases* very slowly up to a large angle of incidence, (less than 75°,) and then increases up to 90°, where there is total reflexion. This singular fact, that the intensity decreases with the obliquity of incidence, was discovered by Mr. Potter,[1] whose experiments extend as far as an incidence of 70°. Whether the subsequent increase which appears from the table indicates a real phenomenon, or arises from an error in the empirical formulæ, cannot be determined without more experiments. It should be observed, however, that in these very oblique incidences Fresnel's formulæ for transparent media do not represent the actual phenomena for such media, a great quantity of the light being stopped, when the formulæ give a reflexion, very nearly total.

"The value of $\delta' - \delta$, or the difference of phase, increases from 0° to 180°. When a plane-polarised ray is twice reflected from a metal, it will still be plane-polarized if the sum of the values of $\delta' - \delta$ for the two angles of incidence be equal to 180°.

"It appears from the formulæ, that when the characteristic χ is very small, the value of δ' will continue very small up to the neighbourhood of the polarising angle. It will pass through 90°, when $mm' = 1$; after which the change will be very rapid, and the value of δ' will soon rise to nearly 180°. This is exactly the phenomenon which Mr. Airy observed in the diamond.

"Another set of phenomena to which the author has applied his formulæ are those of the coloured rings formed between a glass lens and a metallic reflector; and he has thus been enabled to account for the singular appearances described by M. Arago in the *Memoires d'Arcueil*, tom. 3, particularly the succession of changes which are observed when common light is incident, the intrusion of a new ring, &c. But there is one curious appearance which he does not find described by any former author. It is this. Through the last twenty or thirty degrees of incidence the first dark ring, surrounding the central spot, which is comparatively bright, remains constantly of the same magnitude; although the other rings, like Newton's rings formed between two glass lenses, dilate greatly with the obliquity of incidence. This appearance was observed at the same time by Professor Lloyd. The explanation is easy. It depends simply on this circumstance, (which is evident from the table,) that the angle $180° - \delta'$, at these oblique incidences, is nearly proportional to cos. i.

"As to the index of refraction in metals, the author conjectures that it is equal to $\frac{\text{M}}{\cos \chi}$."

Undulatory theory.

In concluding our account of the phenomena of Physical Optics, we could have wished to have given a popular account of the undulatory theory of light, and of the explanation which it affords of a great variety of the most interesting phenomena in optics. This however has been done to such an extent by Dr. Thomas Young, in the article Chromatics in this work, and in the article Polarisation by M. Arago, that we would not be justified in entering again upon the subject. Notwithstanding, however, its acknowledged power in accounting for such a variety of facts, there are many of the principal phenomena in optics of which it is not capable of giving the least explanation; and there are others to which it seems in its present form to be totally inapplicable. We look forward, however, with much hope, to the labours of Professor Lloyd, and Professor Maccullagh, and Professor Powell, in this country, who, in place of checking the progress of enquiry, as has been lately done, by declaring the theory of undulations to be

[1] See *Edinburgh Journal of Science, N. S.* Oct. 1830, vol. iii. p. 278.

Explanation of natural phenomena.

already capable of explaining every phenomenon, regard it as still imperfect even as a mathematical representation of the phenomena, and consider experimental research as the only means by which a true theory of light can be obtained.

PART VIII. ON THE APPLICATION OF OPTICS TO THE EXPLANATION OF NATURAL PHENOMENA.

As several of the subjects which belong to this branch of Optics have been treated pretty fully in other parts of this work, we must confine our attention to topics which have not been previously discussed.

Sect. I.—*On the Rainbow.*

Rainbow.

Fig. 104.

A general description of the rainbow has already been given among the optical phenomena in Meteorology. In order to explain the progress of the rays of light which form the two bows, let R, R, R, R, fig. 104, be parallel rays proceeding from the sun, situated at the back of the observer, placed at O, and let them fall on drops of rain E, F, G, H, in front of the observer. Some of these rays of light will enter the spherical drops of rain, and those which fall perpendicularly and nearly so, will be transmitted through the drop, and of course never reach the observer at O. Other rays, however, especially those which fall obliquely, will be separated into the prismatic colours at the first refraction, and will subsequently be reflected *once*, *twice*, and more times, within the drop, and emerge after *one*, *two*, or more reflexions in different directions. Now, it is obvious that there will be some position of the drops, such as E, F, at which rays that have suffered *one* reflexion will reach the eye of the observer at O. Drops above these will throw the rays which they refract after one reflexion above O, and drops below these will throw the same rays below O. In like manner, there must be some position, as at H and G, at which other drops in which the light that has suffered two reflexions will fall upon the eye at O, the drops above these throwing the rays above, and the drops below them throwing the rays below O. Now, each drop forms by refraction a prismatic spectrum, or coloured and elongated image of the sun. The rays RE, RF, which reach the eye at O, must fall upon the lower drops E, F, on their upper side, as shewn in the figure, and consequently (as may be found by tracing the rays through the drops) the spectrum which they form will have the red rays uppermost, as at r, near F, and the *violet* rays downwards, as at v, near E; and as the same effect will be produced from all the other drops which reflect the sun's rays to the point O, there will appear to an eye at O, a coloured bow, such as we see it in the heavens, with all the colours of the spectrum, as if they had been formed from the sun's image, by a prism of water that produced the same degree of refraction. In like manner, the rays that enter the lower side of the drops will form an inverted spectrum, after *two* reflexions, in which the *red* rays are below, and the *violet* ones above, and as this spectrum is much fainter, it will give a second coloured bow, fainter than the first, and having its red side below, and its violet side above. The following are the dimensions of the two bows:—

Radius of the *red* edge of the *inner* bow....	42°	2′
——— *violet* edge..........................	40	17
Breadth of the inner bow......................	1	45
Radius of the *violet* edge of the *outer* bow	54	7
——— *red*..	50	57
Breadth of the outer bow............................	3	10
Distance between the bows..........................	8	55

Dr. Halley has shewn that the solar rays which suffer *three* reflexions, will form a bow round the sun at the distance of 40° 28′, and that those which suffer *four* reflexions will form a bow at the distance of 45° 33′ from the sun; but the light which reaches the eye after so many reflexions is too faint to be seen, and these bows have consequently never been discovered.

Explanation of natural phenomena.

Supernumerary *bows* of red and green light, to the number of *three*, have been seen in contact with the violet arch of the inner bow, and we have seen them also on the outside of the outer or secondary bow. The cause of these is not known, but a very ingenious explanation of them has been given in Chromatics, vol. xi. p. 634, sect. iii.

Sir David Brewster, upon examining the two rainbows with a rhomb of Iceland spar, found that they consisted wholly of *light polarised* in the plane of reflexion within the drop, or in planes coincident with the radii of the bow. The two bows present a case of *conical polarisation*, the part of the bow vanishing as the principal section of the rhomb becomes parallel to its radius. It is strange that the polarisation of the bow, and consequently of light, had not been discovered when it happened to be seen by reflexion on panes of glass, or other reflecting substances, lying with their planes of reflexion perpendicular to the planes of reflexion within the drop, and near the angle of maximum polarisation. See Meteorology, vol. xiv. p. 749.

Sect. II.—*On Halos and Parhelia.*

The name of *halos* and *parhelia* have been given to circles round the sun and moon, some of which are extremely complicated and beautiful. The general theory of this class of phenomena has been given by Dr. Young, in the article Chromatics, vol. vi. p. 634, sect. ii., and a description of the phenomena themselves, in the article Meteorology, vol. xiv. p. 749.

Artificial halos.

The production of halos, which have their origin in the refraction and reflexion of crystals of ice floating in the atmosphere, may be illustrated by the following method given by Sir David Brewster. A few drops of a saturated solution of alum spread over a plate of glass, so as to crystallise rapidly, will cover the glass with an imperfect crust, which is composed, when examined by the microscope, of flat octohedral crystals, scarcely visible to the eye. If the observer places his eye behind this plate, and close to its smooth side, he will see the sun or the candle encircled with three fine halos, placed at different distances. The interior one, which is the whitest, is formed by the refraction of the rays through two of the faces that have the least inclination to each other, and consequently give a spectrum in which the colours are not greatly dispersed; and as a similar pair of refracting planes lie in every direction, there will be a spectrum in every direction, and consequently a rainbow of a circular form. The second halo, which is *blue* without and *red* within, with all the intermediate prismatic colours more highly dispersed, is formed by a pair of faces more inclined. The third halo, which is larger and more brilliantly coloured, is produced by a third pair of refracting planes, having a greater refracting power, and consequently giving a higher dispersion. When the granular crystals have double refraction, and when they crystallise with their axes perpendicular to the plates, combinations of greater variety and beauty will be produced.

We have endeavoured, by looking through hoar frost upon glass, to produce halos actually resembling those seen in nature; but we have not succeeded, though we have no doubt that it may be effected by causing vapour deposited under a variety of circumstances, to be frozen in different ways.

Sect. III.—*On the Unusual Refraction of the Atmosphere.*

One of the most interesting applications of optical science

Explanation of natural phenomena.

is the explanation which it affords of the extraordinary phenomena which arise from difference of density in different parts of the atmosphere. As this subject has been treated very fully in our article METEOROLOGY, vol. xiv., and illustrated with some interesting figures, we shall confine ourselves at present to an account of the most extraordinary of all the phenomena of this kind which have been observed and correctly described. It was observed by Dr. Vince, on the 6th of August 1806, about seven o'clock in the evening. Between Ramsgate and Dover there is a hill, over which the tops of the four turrets of Dover castle are usually seen to a person at Ramsgate. At the time above mentioned, however, Dr. Vince, when at Ramsgate, not only saw the four turrets *v*, *x*, *w*, *y*, but the *whole of the castle*, *m*, *n*, *s*, *r*, appearing as if it were situated on the side of the hill next to Ramsgate, and rising as much above the hill AB as usual, *as if it had been brought over and placed on the Ramsgate side of the hill*, fig. 105. This appearance continued about twenty minutes. Between Ramsgate and the land from which the hill rises, there is about six miles of sea, and from thence to the top of the hill about the same distance, the height of the eye above the surface of the sea being about seventy feet. It is a very singular circumstance in this phenomenon, that the image of the castle was so very strong and well defined that the hill itself did not appear through the image.

Fig. 105.

In order to explain this phenomenon, Dr. Vince supposes AB, fig. 106, to represent the castle, FC the cliff of Ramsgate, BTD the hill, DC the sea, E the place of the spectator, T the top of the hill, A*yv*E a ray of light coming from the top of the castle to the observer, and B*xw*E another ray coming from the bottom of the castle, and T*xz*E a ray from the summit of the hill, reaching the eye at E, in a direction between those of the other two rays; then it is obvious that such a disposition of the rays will produce the observed appearance. In order to give such a refraction, the density of the air between *yv*E and *xw*E must have varied with great rapidity, so as to increase the curvature of the ray T*xz*E, after it cuts B*w*E in *x*, in order to make the ray T*xz*E fall between the other two rays. See *Edinburgh Transactions*, vol. vi. p. 245.

Fig. 106.

SECT. IV.—*On the Colours of the Atmosphere.*

Colours of the atmosphere.

As the earth's atmosphere acts upon light like all other transparent bodies, and is continually changing its chemical, mechanical, and hygrometrical condition, it acts upon light in very different ways, under different circumstances. As the colour of the sky is absolutely black on the tops of the highest mountains, its blue colour in the regions which we inhabit is owing to the action of the atmosphere.

That the *blue* light of the sky is light that has suffered reflexion from the particles of our atmosphere, is proved by the fact observed by Sir David Brewster, that this blue light is polarized in a plane passing through the observer's eye and the sun. This fact is well illustrated by the discovery which we owe to the same author, of *atmospheric lines* in the spectrum, formed by the blue sky. These lines are principally in the more refrangible spaces, as already described, and hence the prevailing light is blue.

The splendid colours which mark the rising and the setting of the sun, varying from the deepest *red* to *orange*, *yellow*, and even *green*, arise from the same cause; for when we analyse these various lights with the prism, we find that they are owing to definite parts of the spectrum having been absorbed by the atmosphere.

Blue shadows.

The phenomenon of blue shadows is finely seen when the sky is particularly blue. It arises solely from the shadows being illuminated by the blue sky, while the part round the shadow is illuminated by the sun, or by the light of a candle. If the light of the sun passes at the time through vapours so as to make it yellow or orange, the contrast of the shadow is still more striking and beautiful. The light of a candle which contains a great excess of red light, and which may be made to contain more by letting it burn with a long wick, exhibits along with the light of the sky the phenomenon of blue shadows in great perfection.

The subject of the blue colour of the sky has been treated at considerable length in our article on METEOROLOGY, vol. xiv. p. 760, and an instrument called a *Cyanometer*, for measuring its blue colour, has been well described, and an account of the experiments made with it fully detailed.

SECT. V.—*On the Colours of Natural Bodies.*

Colours of natural bodies.

The splendid colours which appear in the natural world have long attracted the attention of philosophers; but no person ever had the courage to give a philosophical theory of them but Sir Isaac Newton. When he had completed his analysis of the colours of thin plates, he conceived that they furnished the true cause of the colours of natural bodies. If we take a thin film of mica, a few millionths of an inch in thickness, it appears to the eye of a bright blue colour. Sir Isaac Newton maintained, that if this film could be cut into a great number of minute parts of the same thickness as itself, these particles would "keep their colour, and a heap of them constitute a mass or powder of the same colour which the plate exhibited before it was broken." A plate of mica of a different thickness, would be *green*, another *yellow*, and another *red*, and all these, if broken down into particles "of the same thickness with the plates," would of course, according to our author, give a *green*, a *yellow*, or a *red* mass.

We have already seen that different thickness of a transparent plate like mica, give various orders of colours; each different tint corresponding with a particular thickness. Considering then the particles of all bodies whatever as transparent, and as having different sizes, they will produce colours corresponding to these different sizes, and consequently we shall have as great a variety of tints in nature as there are varieties in the sizes of the particles of bodies. A difficulty, however, here presents itself. The colours arising from thin plates vary rapidly by inclining them to the incident light, whereas those of coloured media suffer no such change. Hence Sir Isaac Newton, was driven to the supposition that the particles of bodies have such an enormous refractive power, that the paths of the rays refracted by a parallel film will not differ much in length from, and consequently not be very oblique to, a perpendicular line. After explaining this theory, Sir Isaac ventures to affix to different natural colours the order to which they belong, the very tint of that order, and consequently the thickness of the particles which produce the colour. He says, for example, that the *green* colour of all vegetables, the most general tint in nature, is a GREEN of the *third* order, and that the *blue* colour of the sky is a *blue* of the *first* order. Now we know the composition of a *green* of the *third* order, and of a *blue* of the *first* order, as given by Sir Isaac Newton himself. The *green* of the *third* order "is principally constituted of *original green*, but not without a mixture of some *blue* and *yellow*;" that is, it consists of all the rays of the green space, with the least refrangible rays of the *blue* space, and the most refrangible rays of the *yellow* space, and it does not contain a single ray of *indigo*, *violet*, *orange*, or *red* light.

Such being the case, it occurred to Sir David Brewster that the green colour of plants could be accurately analysed by the prism, and having extracted by means of alcohol the green juice of a great variety of vegetable bodies, he analysed their colours by the prism. In all bodies he found the composition of this green colour to be identically the same; but it had no relation whatever to the *green* of the first order. It contained portions of all the colours of the

Explanation of natural phenomena.

spectrum; and the prismatic spectrum seen through these green juices was divided unequally into *six* luminous bands of various breadths, separated by dark intervals.[1] In the same manner he found that the *blue* colour of the sky was not a *blue* of the *first* order.

From a series of experiments in which the same author has been engaged, he has been led to the conclusion that absorption is the cause of this extensive class of colours; and that all the colours of natural bodies arise from the interference of light, by which certain rays are extinguished. When the interference takes place as in thin plates, between the light reflected from the two surfaces, and between the direct transmitted ray and other transmitted rays which suffer reflexion within the thin plates, we have two colours complementary to each other; but even in this case, when the number of films is great, as in decomposed glass, the transmitted colours lose all their resemblance to the colours of thin plates, while the reflected tints are exceedingly brilliant and metallic in their lustre.[2]

In coloured fluids and coloured glasses, and coloured gaseous media, the interference arises from rays that acquire different velocities in passing through the coloured medium, one part of the intromitted light passing through the particles, and the other through the intervening spaces. Hence there are no reflected tints in such coloured media.

Those who wish to study the Newtonian theory of the colours of natural bodies, are referred to Biot's *Traité de Physique*,[3] where it is illustrated and defended with all the sagacity and talent of that distinguished philosopher. See also an account of various ingenious experiments hostile to the theory, in a paper by Mr. Delaval in the *Manchester Memoirs*, vol. ii. p. 131.

SECT. V.—*On the Eye and on Vision.*

In our article on ANATOMY,[4] we have already given a full description of the organ of vision, and Plate XXXIII, fig. 3, exhibits a fine section of the eye after Soemmering. The following dimensions of the eye have been given by Dr. Thomas Young, the measures being taken with great care from his own eye:

	Hundredths of an inch.
Length of optical axis	91
Vertical chord of the cornea	45
Versed sine of ditto	11
Horizontal chord of the cornea	49
Aperture of the pupil seen through the cornea	27 to 13
Diminished in consequence of the magnifying power of the cornea	25 to 12
Radius of the anterior surface of the crystalline lens	30
Radius of the posterior surface	22
Distance of the optical centre from the anterior surface of the lens	10
Distance of the optical centre of the lens from the cornea	22
Focal length of the cornea for objects 10 inches distant	115
Joint focus of cornea and lens 91—22=	69
Principal focal distance of lens	173
Distance of the centre of the optic nerve from the point opposite the pupil	11
Range of the eye, or field of vision	110

The following measures of the crystalline lens and cornea were taken by Sir David Brewster and Dr. Gordon, from the eye of a female, above fifty years of age, a few hours after death.

Diameter of the crystalline	0·378
Diameter of the cornea	0·400
Thickness of the crystalline	0·172
Thickness of the cornea	0·042

The following measures of the refractive powers of the humours of the eye, were taken by the same authors from the same eye:

	Index of Refraction.
Refractive power of water	1·3358
Ditto of aqueous humour	1·3366
Ditto of vitreous humour	1·3394
Ditto of outer coat of crystalline	1·3767
Ditto of middle coat of ditto	1·3786
Ditto of central part of ditto	1·3990
Ditto of the whole crystalline	1·3839

The following measures may be occasionally useful:

	Index of Refraction.
From aqueous humour into the crystalline	1·0466
Do. do., taking the mean index of the crystalline,	1·0353
From the crystalline into the vitreous humour	0·930

Vision.

If we execute a large diagram of the eye, and by means of the above indices of refraction trace the progress of parallel rays from the cornea to the retina, we shall find that they converge to points in or near to that membrane. The increase of density in the crystalline lens towards its centre is calculated to correct the spherical aberration, by bringing the central rays to the same focus with the marginal rays; but there is no provision in the eye for correcting the aberration of colour, because the purposes of vision do not require it to be corrected. It may be readily proved by tracing the rays diverging from both extremities of any object to the retina, and it may be also shewn by direct experiment, that an inverted image of the object is formed upon that membrane. Now, it is a law of vision, that when a ray of light falls upon any point of the retina, the mind infers that the ray proceeded from a point in some line perpendicular to that point of the retina. Hence, as rays from the upper part of an object fall upon the lower part of the retina, and *vice versâ*, such rays will seem to proceed from the upper part of the object, and all points of an object will be seen in the direction of the rays which issue from them, and consequently the object itself *must* appear *erect*, though its image is inverted.

Cause of erect vision

Single vision with two eyes.

As it is a law of vision that an object seen with a single eye is seen in a fixed direction, arising from the form of the retina as a whole, or from the form of its individual parts, then if rays from the same object fall upon another eye, or upon a hundred other eyes which have the power of placing the retina of all the eyes, so as to see the same object in the same direction, then the object thus seen must appear single. The only difference will be, that the object will be seen twice as bright with two eyes, and a hundred times as bright with an hundred eyes. If we place a hundred shillings in the same straight line, an eye whose axis coincides with the axis of the cylinder which they compose, will only see one shilling, and the same effect would be produced if the shillings were transparent. If the hundred eyes were placed with their axes in a hundred different directions, an hundred objects will be seen. Small objects are seen double and even triple with one eye when the crystalline lens is not uniform in its refractive power.

Origin of squinting.

The defect of squinting may arise from several causes. It may be an original defect, in which the *axis of the eye*, or the line in which objects are seen most distinctly does not pass through the centre of the pupil. In this case it is incurable: but it is generally speaking a disease arising from an imperfection in one eye, from its having a different focal length from the other, from its giving a less distinct vision of objects, or from its muscles not being able to direct it as quickly as the other to visible objects. The consequence of this is, that as the observer can do without it, and uses only his best eye, the imperfect one does not follow the movements of the other, and therefore squints.

Indistinctness of oblique vision.

When we wish to see any object very distinctly, we invariably direct to it the axis of the eye, and it is a curious fact that there is no retina at the point where the axis meets the back of the eye, the *foramen centrale* corresponding to the

[1] See *Edinburgh Transactions*, vol. xii. [2] *Phil. Trans.* 1837, p. 245. [3] Tom. iv. p. 123. [4] Vol. ii. p. 798.

Explanation of natural phenomena.

extremity of the axis. When the eye thus sees an object with perfect distinctness, every other point of the same object is seen indistinctly, and there is no adjustment of the eye by which distinctness of vision can be obtained at any distance from the axis of the eye, the only way of seeing disinctly being to direct the axis to the point we wish to examine. The preceding fact leads to the opinion, that parts of an object seen in the retina cannot be seen distinctly, and yet if this were the case, we should be able to perceive upon an uniform ground the *foramen centrale.*

Indistinct vision at the base of the optic nerv

The opinion that the retina, though sensible to light, does not give perfectly distinct vision, is favoured by the fact, that when the image of any object falls upon the round base of the optic nerve, shewn in Plate XXXIII. fig. 3 of ANATOMY, the object is not distinctly visible. This may be easily proved by fixing on the wall of a room, at the height of the eye, three wafers each *two* feet distant. Stand in front of the middle wafer with one eye shut, and beginning near the wall, withdraw gradually from it, (continuing to view the *left* hand wafer if the *right* eye is open, and the *right* hand wafer if the *left* eye is open,) till the middle wafer vanishes. This will be found to take place at *five* times the distance from the wall at which the wafers are placed, that is, at the distance of *ten* feet in the present case. If we use three candles, the middle one will not vanish like the wafer, but will become a cloudy mass of light.

Occasional insensibility of the retina in oblique vision.

The occasional insensibility of the retina to objects seen obliquely, was discovered by Sir David Brewster, who has illustrated it in the following manner. If we fix one eye on a particular point, such as the head of a pin stuck into a green cloth, and lay down a quill or strip of paper upon the green cloth, some inches distant from the pin, and then keep looking steadily at the pin's head, part of the quill, or the whole of it, will occasionally disappear, as if it had been wholly removed from the cloth. In a short time it will reappear, and again vanish. The very same effect is produced, though less readily, when both eyes are used, and when a luminous body is used in place of the quill. In this case the luminous body does not disappear, but expands into a mass of nebulous light, which is of a *bluish white* colour, encircled with a bright ring of *yellow* light.

Superior brightness of objects seen obliquely.

But though we cannot see objects distinctly by oblique vision, yet they appear much brighter, and minute objects, especially luminous ones, are more easily seen by turning the axis of the eye away from them. Various astronomers have found that very faint stars, and the satellites of Saturn, which disappear when the eye is turned fully upon them, may be distinctly seen by directing the eye to another part of the field. This effect seems to arise from the expansion and enlargement of luminous points seen obliquely.[1]

On the seat of vision.

It has long been disputed, but the question has not been much agitated in modern times, whether the retina or the choroid coat behind it is the seat of vision. The insensibility of the base of the optic nerve, and the fact that vision is most distinct where there is no retina, are arguments in favour of the choroid coat being the seat of vision, as Mariotte believed. The transparency of the retina, and the opacity of the choroid coat were considered as additional arguments in favour of that opinion. Dr. Knox has shewn, that in the eye of the cuttle fish, there is a membranous opaque pigment in front of the retina, so that in this case the retina must receive the influence of light from the vibrations of this membrane just as it may receive them in other cases, from the same membrane placed behind it. M. Lehot, a living French author, has endeavoured to shew that the vitreous humour is the seat of vision; that we see the length, breadth, and thickness of every object as we do an image formed in smoke; and that the retina takes cognizance of this image in its three dimensions, by nervous filaments extending so far into the vitreous humour as to render any adjustment of the eye at different distances unnecessary.

Insensibility of the eye to faint light.

The insensibility of the retina to direct impressions of faint light, was discovered by Sir David Brewster,[2] who found, that when the eye directed its axis to objects faintly illuminated, it could not keep up a sustained vision of them. They disappeared and reappeared, and the eye was thrown into a state of painful agitation.

Duration of impressions on the retina.

When we shut the eye quickly after looking at an object, we see it for an instant (about the *seventh* part of a second) in its own colours; but this impression is instantly followed by an image of the object in its complementary colours. If we look at a window at the end of a long passage, we first see, after shutting our eyes, a picture of the window, with *black* bars and *white* panes; but after the *seventh* of a second the picture is one with *white* bars and *black* panes. When we whirl a burning stick, we see a complete circle of red light, although the burning end of the stick can only be in one part of the circle at the same instant. This affection of the retina is the principle of Dr. Paris's pretty toy, called the *Thaumatrope*, or *Wonder-turner*. A circular card with two strings is made to whirl rapidly round one of its diameters. If we draw a cage on one side of a card, and a bird on the other, and whirl the card round, we shall see the bird within the cage, the retina retaining the impression of both even when none of them are seen, which is the case when the edge of the card is directed to the eye.

Dr. Paris's thaumatrope.

Phenakistoscope or magic disc.

The same property of the retina to preserve impressions of light, is the principle on which that beautiful instrument, called the phenakistoscope, or magic disc, is founded. This instrument was, we believe, originally invented by Dr. Roget, and improved by M. Plateau, at Brussels, and Mr. Faraday. It consists of a circular disc from six to twelve inches in diameter, with rectilineal apertures on its margin in the direction of its radii. A series of figures, of a rider for example, leaping a fence, is drawn on the circumference of a circle, parallel to the rim of the disc. The *first* figure represents the rider and horse standing *before* the fence; and the *last* figure represents them standing *over* the fence when the leap is completed. Between these two figures there are several others, representing the rider and the horse in different parts of the leap. The observer then stands in front of a looking-glass, with the disc in his left hand, attached to a handle, and by a piece of simple mechanism he whirls it rapidly round, looking at its image on the glass through the notches in its margin. He is then surprised to see the horse and his rider actually leaping the fence, as if they were alive, and returning and leaping again as the disc revolves. If we look over the margin of the disc, at the reflected picture on the face of the disc, all the figures are effaced, and entirely invisible; but when we look through the notches, we only see the figure of the horse and rider at the instant the notch or aperture passes the eye, so that the picture instantaneously formed on the retina is not obliterated by preceding or subsequent impressions. Hence the eye receives in succession the pictures of the horse and rider in all the attitudes of the leap, which are blended, as it were, into one action. The apparent velocity with which the horse and rider advances (supposing the disc always to have the same velocity) depends on the proportion between the number of apertures in the margin of the disc, and the number of figures of the horse and rider.

If we use a disc with three concentric circles of apertures, each containing different numbers, 8, 10, and 12, for example, then considering that these apertures revolve in the opposite direction in the reflected image, it is obvious that when we look through the circle of 10, which moves from left to right at the image of 10, revolving in the mirror from right to left, these opposite motions will de-

[1] See *Lond. and Edin. Phil. Mag.* Sept. 1832, p. 169.

[2] *Edinburgh Journal of Science*, No. vi. p. 288.

stroy each other, and the circle of 10 apertures will appear to stand still in the picture. On the other hand, the circle of 12 apertures will always gain upon the one of 10, from which we look, and will appear to move from left to right, with the difference of the velocities of the two, while the one of 8 will move backwards with the same difference.

If we whirl a disc containing any word or figure upon it, without using a reflector, all is confused, and we cannot read the word or see the figure. Let it be whirled, however, in the dark, and let a spark of electricity, or the light of a little inflamed gun-powder, or of a percussion-cap, illuminate the disc, which it does only for an instant, and during that short instant, the word or figure will be seen to stop, and we shall read the one and see the other with great distinctness.

When objects are placed at different distances, the focus or point of distinct vision in the eye must vary. We feel that the eye has the power of adapting itself to these different distances, so as to make the picture on the retina always distinct. How this is done has been long a matter in dispute. There can be no doubt, however, that the first step in the process is the variation of the pupil, which seems by a mechanism at the base of the iris to increase the distance of the lens from the retina.

At the age of about forty, the eye loses this power of adaptation in consequence of the flattening of the crystalline lens, which renders it necessary to use a convex glass, which just compensates the flatness of the lens, and permits the eye to adjust itself as formerly. The opposite state of the eye, not produced by age, but rather diminished by it, is common even in young persons, arising either from a too great convexity or refractive power in the lens, or too great convexity in the cornea. In this state of the eye, the image is formed in front of the retina, and a concave lens is necessary to correct it. This is called *short-sightedness*, which almost always decreases by age in consequence of the crystalline lens becoming flatter.

When the eye looks steadily at a bright coloured *red* wafer, and then looks at the white paper on which the wafer lies, it will see for a while a *green* one, the green being the *accidental* colour, or the *complementary* one to the *red*. The *green* image is called an *ocular spectrum*, as it has no real existence. The *accidental colours* and the original colours are the same as those given in Newton's Table, p. 432, where the *reflected* tints correspond with the original or *red* colour of the wafer, and the *transmitted* ones to the accidental colour, or *vice versa*; so that we can determine from that table the accidental colours of any coloured object upon which the eye may look steadily.

When the eye looks at the sun, or a bright image of it, the ocular spectrum is not *black*, but of various colours in succession, each colour being surrounded with a rim of its accidental colour.

The following beautiful experiment, shewing the effect of light in diminishing the sensibility of the retina to particular colours, we owe to Mr. Smith, surgeon at Fochabers. Hold a slip of white paper vertically about a foot from the eye, and direct both eyes to an object beyond it, the slip will appear double, and the two images equally white. Let a candle be brought near the right eye, so as to act strongly upon it, without affecting the left, then the *left* image of the paper, or that seen by the right eye, will grow *green*, and the *right* hand image, or that seen by the *left* eye, will grow *red*, forming a beautiful contrast of colours. If the candle is brought round to the left eye, the images will first become of the same whitish colour, and then the *right* hand one will become *green*, and the left hand one *red*.[1]

The insensibility of the eye to particular colours is very uncommon. Professor Dugald Stewart, Dr. Dalton, and Mr. Troughton, were unable to distinguish the colours at the red end of the spectrum. All red objects appeared green, owing to the insensibility of their retinas to red colours. This subject has already been treated of in our article on Colours, vol. vii. p. 128.

Optical instruments.

PART IX. DESCRIPTION OF OPTICAL INSTRUMENTS.

Optical instruments.

The great number of optical instruments which have been described in different parts of this work, renders it scarcely necessary to treat this subject in the general article. Under the articles Burning Instruments, Camera Lucida, Kaleidoscope, Micrometer, Microscope, Photometers, and Telescope, the reader will find the information, some of which he might have expected here. There are instruments, however, so intimately connected with Optics, and not previously described, which we must shortly notice, namely, the *Cylindrical Mirror*, the *Camera Obscura*, the *Magic Lantern*, and the *Phantasmagoric Machine*.

1. *Cylindrical Mirror.*

Cylindrical mirrors. Fig. 107.

We have already (see p. 382) described the principle of cylindrical mirrors. If we suppose one of these mirrors, AB, fig. 107, to be placed on a table, with the portrait of any person laid before it on the table, the reflected picture of the portrait in the cylindrical mirror will be distorted. If we take an accurate drawing of this distorted picture and lay it before a cylindrical mirror, as shown at MN, where the human form can scarcely be recognised, we shall see in the cylindrical mirror its image reduced to symmetry.

2. *On the Camera Obscura.*

Camera obscura.

We have already explained the principle of the camera obscura in treating of the images formed by convex lenses. The instrument is indeed nothing more than a convex lens placed in a suitable box, on the side or bottom of which an image of external objects is formed by the lens.

Fig. 108.

A convenient portable camera obscura for drawing objects is shown in fig. 108. The external object or landscape is reflected down into the lens AB by an inclined mirror CD. The rays thus falling vertically upon the lens, are refracted to their foci, and form a distinct image of the landscape on the paper placed at EF. On one side of the box there is an opening through which the observer introduces his head and hand, care being taken, by a curtain of black cloth behind him, to exclude all extraneous light. M. Cauchoix of Paris has found that the best form of the lens for a camera is a meniscus, having its convex surface towards the image, and its concave surface towards the object, and their radii of curvature as 5 to 8.

3. *On the Magic Lantern.*

Magic lantern. Fig. 109.

The magic lantern, an invention of the celebrated Athanasius Kircher, is shewn in fig. 109. It consists merely of a lens AB, which forms on the wall of a dark room a picture of any object placed before it, and at a greater distance than its anterior principal focus. The light of an argand lamp is thrown in a condensed state by the illuminating lens D, upon transparent varnished pictures painted on long sliders. The lens AB forms a large circle of light upon the wall, which, if it is not smooth and white, should be covered with a white smooth cloth, and the images of the coloured figure appear within this circle.

A magic lantern is the same as a solar microscope, the

[1] An analysis of this and similar experiments will be found in the *Lond.* and *Edin. Phil. Mag.* Ed. 1832, p. 249.

Optical instruments || Optimates.

sun being used for the source of light in the latter case, and natural objects in place of pictures. The *solar camera microscope* invented by Dr. Goring, and fully described in our article MICROSCOPE, vol. xv. p. 46, and the *oxyhydrogen microscope*, described in the same article, may be considered as the most perfect magic lanterns that have been constructed, there being no difficulty in adapting them to give magnified representations of minute transparent paintings.

4. *On the Phantasmagoric Apparatus.*

Phantasmagoric apparatus.

The apparatus for the *phantasmagoria*, or the raising of spectres, is nothing more than a magic lantern mounted upon wheels, which, in place of throwing its pictures upon an opaque white ground, upon which the spectator looks, throws them upon one side of an imperfectly transparent screen, the spectator viewing them on the other side of the screen. The direct light of a lamp A, fig. 110, and the light reflected from the concave mirror B, is thrown upon the two illuminating lenses C, D, which condense it, and thus strongly illuminate the spectres and figures painted upon sliders at E. These sliders are placed a little before the anterior focus of the magnifying lens F, which forms a highly magnified picture of the figures on the transparent screen at G. When this apparatus is mounted upon a carriage with wheels, as at H, it may be made to approach to, or recede from, the screen G, in consequence of which the figures may be made to contract into dwarfs, disappearing in a point of light, or swell out into giants of enormous magnitude. In order, however, to have the pictures distinct at different distances of the apparatus from the screen, an adjustment is necessary, to make the distance EF increase as the apparatus approaches to G, and diminish as it recedes from it. With this view, the lens F is fixed to a slider, which may be drawn out by the general frame H. When this frame H is drawn away from the screen, the point K is brought lower by means of the rod IK, connected with another rod KN fixed to the frame of the screen at N, where there is a joint or centre of motion. The descent of the point K causes another lever KL to move the horizontal slider (which carries the lens F) in such a manner as to keep the screen always in the focus of F, and consequently the picture upon it always distinct. When the frame H, on the other hand, advances to the screen, the point K rises, and the lens F is again adjusted by the motion of the slider. When the images diminish and appear to vanish, the support of the lens F permits the screen M to fall and intercept part of the light. The screen M may have a triangular opening, so as to uncover the middle only of the lens F. In this adjusting apparatus the rods KN and KL must be equal, and the point I must be twice the focal length of the lens F before the object, L being immediately under the focus of the lens. The object of the screen M is to diminish the illumination of the objects as they get smaller and appear to retire from the spectator, because in the instrument they actually become brighter.

Fig. 110.

When M. Robertson exhibited this remarkable instrument, living persons were often strongly illuminated and introduced into the picture. The effect of life, however, was better given when the shadows of living objects only were introduced.

For farther information on the subject of this article, see ASTRONOMY, vol. iv. p. 101, chap. iv. ACHROMATIC TELESCOPES, BURNING INSTRUMENTS, CAMERA LUCIDA, CHROMATICS, COLOURS, KALEIDOSCOPE, METEOROLOGY, MICROMETER, MICROSCOPE, PHOTOMETER, and TELESCOPE.

OPTIMATES, one of the divisions of the Roman people, and opposed to *populares*. It is not easy to ascertain the characteristic differences of these two parties. Some say the *optimates* were warm supporters of the dignity of the chief magistrate, and promoters of the grandeur of the state, caring not if the inferior members suffered, provided the superior powers were advanced; whereas the *populares* boldly contended for the rights of the people, claimed larger privileges, and laboured to bring matters nearer to an equality. In short, according to this account, they resembled the court and country parties amongst the people of this island. Cicero says that the *optimates* were the best citizens, who wished to deserve the approbation of the better sort; and that the *populares* courted the favour of the populace, not so much considering what was right, as what would please the people and gratify their own thirst of vain-glory and applause.

OPTIO, an officer in the Roman army, who was an assistant or lieutenant to the centurion. The *optio* was so called because in later times he was the choice or option of the centurion; at first, however, he derived his appointment from the tribune or commander of the legion. Sometimes the *optiones* were also called *succenturiones* and *tergiductores;* the latter name having been given them because their post was in the rear of the company. Several authors mention *sub-optiones* or sub-lieutenants. It is proper, however, to add, that *optiones* were not peculiar to the camp, but were also employed in a variety of other offices.

OR, the French word for gold, by which this metal is expressed in heraldry. In engraving it is denoted by small points all over the field or bearing.

ORA, in *Antiquity*, was a term equivalent to ounce; but it has been much debated amongst our antiquaries, whether the ora, the mention of which so often occurs, was a coin, or only money of account. Dr Hickes observes, that the mode of reckoning money by marcs and oras was never known in England until after the settlement of the Danes; and by examining the old nummulary estimates amongst the principal Gothic states upon the Baltic, it appears that the ora and *solidus* were synonymous terms, and that the ora was the eighth part of the marc. From several of the Danish laws, it likewise appears that the Danish ora, derived by corruption from *aurea*, was the same as the Frank *solidus* of twelve pence. As a weight, the ora was regarded as the *uncia* or unit, by which the Danish marc was divided; and in Doomsday-book the ora is used for the ounce, or the twelfth part of the nummulary Saxon pound, and the fifteenth of the commercial. As a coin it was an *aureus*, or the Frank *solidus* of twelve pence; and from the accidental coincidence of the Frank *aureus* with the eighth part of the marc, the Danes probably took occasion to give it the new name of ora. Another ora is mentioned in the rolls of the 27th of Henry III. the value of which was sixteen pence; and this was probably derived from the half mancus of the Saxons, as there were no *aurei* of that period to which these two denominations of money of sixteen and twelve pence could possibly be ascribed. It may be further observed, that the name ora distinguishes the gold coins in several parts of Europe to this day. The Portuguese moidore is nothing else but *moeda d'oro*, from the Latin *moneta de auro;* the French *louis d'or* comes from the same use of the word, and owes its appellation to the ora.

ORACLE, amongst the heathens, was the answer which the gods were supposed to give to those who consulted them upon any affair of importance. It is also used for the god who was thought to give the answer, and for the place where the response was given.

The credit of oracles was so great that in all doubts and disputes their determinations were held as sacred and inviolable. Hence vast numbers flocked to them for advice about the management of their affairs; and no business of any consequence was undertaken, scarcely any peace concluded, any war waged, or any new form of government instituted, without the advice and approbation of some oracle. The answers were usually given by the intervention of the priest or priestess of the god who was consulted; and were generally expressed in such dark and unintelligible phrases, as might easily be wrested to prove the truth of the oracle, whatever the event should happen to be. It is not, therefore, to be wondered at, that the priests who delivered them were in the highest credit and esteem; and that they managed this reputation so as greatly to promote their own particular advantage. They accordingly allowed no man to consult the gods before he had offered costly sacrifices and made rich presents to them. Nor was this all. To keep up the veneration for their oracles, and to prevent their being taken unprepared, they admitted persons to consult the gods only at certain stated times; and sometimes they were so cautious, that the greatest personages could obtain no answer at all. Thus Alexander himself was peremptorily denied by the Pythia or priestess of Apollo, till she was by downright force obliged to ascend the tripos, when, being unable to resist any longer, she cried out, "Thou art invincible;" and these words were accepted instead of any further oracle.

When men began to be better instructed by the lights which philosophy had introduced into the world, the false oracles insensibly lost their credit. Chrysippus filled an entire volume with false or doubtful responses. Œnomaus, to be revenged of some oracle which had deceived him, made also a compilation of responses, to show their ridiculous vanity. Eusebius has preserved some fragments of this criticism on oracles by Œnomaus. "I might," says Origen, "have recourse to the authority of Aristotle and the Peripatetics, to make the Pythoness much suspected; I might extract from the writings of Epicurus and his followers an abundance of things to discredit oracles; and I might show that the Greeks themselves made no great account of them."

The reputation of oracles was greatly lessened when they became an artifice of politics. Themistocles, having the design of engaging the Athenians to abandon Athens, and to embark on board of their ships, in order to be in a better condition to resist Xerxes, made the Pythoness deliver an oracle, commanding them to take refuge in wooden walls. Demosthenes said, that the Pythoness "philippized," to signify that she was gained over by Philip's presents.

The cessation of oracles is attested by several profane authors, as Strabo, Juvenal, Lucian, and others. Plutarch accounts for it, by saying that the benefits of the gods are not eternal as themselves are; that the genii who presided over oracles are subject to death; and that the exhalations of the earth had been exhausted. It appears that the last reason had been alleged in the time of Cicero, who ridicules it in his second book on Divination; as if the spirit of prophecy, supposed to be excited by subterraneous effluvia, had evaporated by length of time, as wine or other liquors by being long kept.

Suidas, Nicephorus, and Cedrenus, relate that Augustus, having consulted the oracle of Delphos, could obtain no other answer but this: "The Hebrew child, whom all the gods obey, drives me hence, and sends me back to hell; get out of this temple without speaking one word." Suidas adds, that Augustus dedicated an altar in the capitol, with this inscription, "To the eldest Son of God." But notwithstanding these testimonies, the answer of the oracle of Delphos to Augustus seems very suspicious. Cedrenus cites Eusebius for this oracle, which is not now found in his works; and the peregrination of Augustus into Greece took place eighteen years before the birth of Christ.

Suidas and Cedrenus also give an account of an ancient oracle delivered to Thulis, a king of Egypt, which they assure us is well authenticated. The king having consulted the oracle of Serapis, to know if there ever was, or would be, one so great as himself, received this answer: "First God, next the Word, and then the Spirit with them; they are equally eternal, and make but one whose power will never end; but do thou, mortal, get thee hence, and think that the end of the life of man is uncertain."

Van Dale, in his treatise of oracles, does not believe that they ceased at the coming of Christ. He relates several examples of oracles which were consulted until the death of Theodosius the Great; and he quotes the laws of the Emperors Theodosius, Gratian, and Valentinian, against those who consulted oracles, as affording certain proof that the superstition of oracles still subsisted in the time of those emperors. But others conceive that the opinion of those who believe that demons had no share in the oracles, and that the coming of the Messiah made no change in them, as well as the contrary opinion of those who pretend that the incarnation of the Word imposed a general silence on all oracles, should all be equally rejected. They allege that two sorts of oracles ought to be distinguished; the one dictated by the spirits of darkness, who deceived men by their obscure and doubtful answers; the other, the pure artifice and deception of the priests of false divinities. As to the oracles given out by demons, the reign of Satan was destroyed by the coming of the Saviour; truth shut the mouth of lies; but Satan still continued his old craft amongst idolaters. All the devils were not reduced to silence at the same time by the coming of the Messiah; it was only on particular occasions that the truth of Christianity and the virtue of Christians imposed silence on the devils. St Athanasius tells the Pagans that they had themselves been witnesses of the sign of the cross having put the devils to flight, silenced oracles, and dissipated enchantments. This power of silencing oracles, and putting the devils to flight, is also attested by Arnobius, Lactantius, Prudentius, Minutius Felix, and several others, whose testimony affords certain proof that the coming of the Messiah had not imposed a general silence on oracles.

Plutarch relates, that the pilot Thamus heard a voice in the air, crying out, "The great Pan is dead;" upon which Eusebius observes, that the accounts of the death of the demons were very frequent in the reign of Tiberius, when Christ drove out the wicked spirits. Indeed the same judgment may be passed on oracles as on *possessions*. It was on particular occasions, by the divine permission, that the Christians cast out devils, or silenced oracles, in the presence, and even by the confession, of the Pagans themselves; and thus it is that we should understand the passages of St Jerome, Eusebius, Cyril, Theodoret, Prudentius, and other authors, who have said that the coming of Christ imposed silence on the oracles.

As to the second sort of oracles, which were pure artifices and deceptions of the priests of false divinities, and which probably exceeded the number of those which immediately proceeded from demons; they did not cease till idolatry was abolished, though they had lost their credit for a considerable time before the coming of Christ. It was concerning this more common and general sort of oracles, Minutius Felix observed, that they began to discontinue their responses, according as men began to be more enlightened. But, however oracles were decried, impostors always found dupes, and the grossest cheats almost never failed to deceive.

Daniel discovered the imposture of the priests of Bel, who had a private way of getting into the temple to take away the offered meats, and who made the king believe that the idol had consumed them. Mundus, being in love with Paulina, the eldest of the priestesses of Isis, went and told her, that the god Anubis, being passionately fond of her, commanded her to give him a meeting. She was afterwards shut up in a dark room, where her lover Mundus, whom she believed to be the god Anubis, was concealed. This imposture having been discovered, Tiberius ordered those detestable priests and priestesses to be crucified, and with them Idæa, the freed-woman of Mundus, who had conducted the whole intrigue. He also commanded the temple of Isis to be levelled with the ground, and her statue to be thrown into the Tiber; but as to Mundus, he contented himself with sending that person into banishment.

Theophilus, bishop of Alexandria, not only destroyed the temples of the false gods, but discovered the cheats of the priests, by showing that the statues, some of which were of brass, and others of wood, were hollow within, and led into dark passages made in the wall.

Lucian, in discovering the impostures of the false prophet Alexander, says that the oracles were chiefly afraid of the subtilties of the Epicureans and the Christians. The false prophet Alexander sometimes feigned himself seized with a divine fury, and by means of the herb sopewort, which he chewed, frothed at the mouth in so extraordinary a manner that the ignorant people attributed it to the power of the god by whom he was possessed. He had long before prepared a head of a dragon made of linen, which opened and shut its mouth by means of a horse-hair. He went by night to a place where the foundations of a temple were digging; and having found water, either of a spring, or of rain which had settled there, he hid in it a goose egg, in which he had enclosed a little serpent that had just been hatched. The next day, very early in the morning, he came quite naked into the street, having only a scarf about his middle, holding in his hand a scythe, and tossing about his hair like the priests of Cybele; then getting on the top of a high altar, he said that the place was happy to be honoured by the birth of a god. Afterwards, running down to the place where he had hidden the goose egg, and going into the water, he began to sing the praises of Apollo and Æsculapius, and to invite the latter to come and show himself to men. At these words, he dipped a bowl into the water, and took out the mysterious egg, which had a god enclosed in it; and when he had it in his hand, he began to say that he held Æsculapius. Whilst all were eager to have a sight of this fine mystery, he broke the egg, and the little serpent starting out, twisted itself about his fingers.

These examples show clearly that both Christians and Pagans were so far agreed as to treat the greater number of oracles as purely human impostures. That in fact *all* of them were so, will perhaps be concluded by those who give equal credit to demoniacal inspiration and demoniacal possession. The most ancient oracle was that of Dodona; but the most famous was that of Delphi, which performs such a prominent part in Pagan antiquity. Another celebrated one was the oracle of Trophonius, in the neighbourhood of Lebadia, a city of Bœotia. It was held in high estimation, and received its name from Trophonius, brother of Agamedes, who lived in a subterranean dwelling near Lebadia, and pretended to possess the faculty of foretelling future events. He died in his cave, and was deified as an oracular divinity. This oracle owed its reputation to one Saon. Those who repaired to this cave for information were required to offer certain sacrifices, to anoint themselves with oil, and to bathe in a certain river. They were then clothed with a linen robe, took a honeyed cake in their hands, and descended into the subterranean chamber by a narrow passage; and here it was that futurity was unfolded to them, either by visions or by extraordinary sounds. The return from the cave was by the same passage; but the persons consulting the oracle were obliged to walk backwards. They generally came out astonished, melancholy, dejected; and hence the proverb *ἐις Τροφωνιου μεμαντευται*. The priests, on their return, placed them upon an elevated seat, called the seat of Mnemosyne, where an account was taken of what they had seen and heard. They were then conducted by their companions to the chapel of good Genius, where, by degrees, they recovered their usual composure and cheerfulness.

Besides these three principal oracles of Greece, it is proper to take notice of that of Amphiaraus at Oropius, in Attica. It was so called from Amphiaraus, the son of Oicleus, a man deeply skilled in magic, the interpretation of dreams, and the like, who, after his death, was deified, and delivered oracles in a temple erected to his divinity. Those who applied for information were required to purify themselves, offer sacrifice, fast twenty-four hours, abstain from wine two days, and make an offering of a ram to Amphiaraus; they were then to sleep on the skin of the animal, and to see their destiny in a dream. Near the temple was the fountain of Amphiaraus, which was deemed sacred, the waters of it being forbidden to be used for ordinary purposes.

At Delos there was also an oracle of the Delian Apollo; in Milesia there was that of the Branchidæ; and there were others of less note, which do not require particular description, such as that of the camps at Lacedæmon, that of Nabarcha, that of Chrysopolis, that of Claros in Ionia, that of Mallos, that of Patarea, that of Pella, that of Phasellides, that of Sinope, that of Orpheus' head, and a few more, which it is unnecessary to mention.

Although the Romans upon many occasions consulted the Grecian oracles, and had but few in their own country, yet we must not omit mentioning the oracles which were delivered by the Sibyl of Cumæ, and enjoyed great celebrity. They have been frequently alluded to by Virgil.

We have hitherto only considered the oracles of false gods, of which there was a far greater number than our limits permit us to enumerate, and before either Greeks or Romans had risen to any distinction. Oracle is in sacred history sometimes used for the mercy-seat, or the cover of the ark of the covenant; and by others it is taken for the sanctuary, or the most holy place, in which the ark was deposited.

Amongst the Jews may be distinguished several kinds of real oracles. They had first oracles which were delivered *viva voce*, as when God spake to Moses face to face, as one friend speaks to another;[1] secondly, prophetical dreams sent by God, as the dreams which God sent to Joseph, and which foretold his future greatness;[2] thirdly, visions, as when a prophet in an ecstasy, being neither properly asleep nor awake, had supernatural revelations;[3] fourthly, the oracle of Urim and Thummim, which was accompanied with the ephod or the pectoral worn by the high priest, and which God had endued with the gift of foretelling things to come.[4] This manner of inquiring of the Lord was often made use of, from Joshua's time till the erection of the temple at Jerusalem. Fifthly, after the building of the temple, they generally consulted the prophets, who were numerous in the kingdom of Judah and Israel. From Haggai, Zechariah, and Malachi, who are the last of the prophets any of whose writings remain, the Jews pretend that God gave them what they call *Bathcol*, or the daughter of the voice, which was a supernatural

manifestation of his will, and was performed either by a strong inspiration or internal voice, or else by a sensible and external voice, which was heard by a number of persons sufficient to bear testimony to the fact. For example, such was the voice that was heard at the baptism of Jesus Christ, saying, " This is my beloved Son, in whom I am well pleased; hear ye him."[1]

The Scripture likewise affords us examples of profane oracles. Balaam, at the instigation of his own avarice, and fearing to lose the recompense which had been promised him by Balak, king of the Moabites, suggested to this prince the diabolical expedient of making the Israelites fall into idolatry and fornication;[2] by which he assured him of a certain victory, or at least of considerable advantage against the people of God.

Micaiah the son of Imlah,[3] a prophet of the Lord, says that he saw the Almighty sitting upon his throne, and all the host of heaven round about him; and the Lord said, who shall tempt Ahab king of Israel, that he may go to war with Ramoth-gilead, and fall in the battle? One answered after one manner, and another after another. At the same time an evil spirit presented himself before the Lord, and said, I will seduce him. And the Lord asked him, how? To this Satan answered, I will go and be a lying spirit in the mouth of his prophets. And the Lord said, Go, and thou shalt prevail. This dialogue clearly proves these two things: first, that the devil could do nothing by his own power; and, secondly, that, with the permission of God, he could inspire the false prophets, sorcerers, and magicians, and thus make them deliver false oracles.

Respecting the cessation of profane oracles, there have been a variety of opinions, some of which we have already noticed. It has been generally held, indeed, that oracles ceased at the birth of Jesus Christ. Yet some have endeavoured to maintain the contrary, by showing that they were in existence in the days of Julian, commonly called the Apostate, and that this emperor himself consulted them; that history makes mention of several laws published by the Christian emperors Theodosius, Gratian, and Valentinian, to punish persons who interrogated them, even in their days; and that the Epicureans were the first who made a jest of this superstition, and exposed to the people the roguery of the priests. As we suspect most of the facts here asserted should be understood in a qualified sense, we shall endeavour to discuss this point of controversy in as few words as possible, although it is undoubtedly a matter of some consequence.

1st, The question, properly stated, is not, whether oracles became extinct immediately upon the birth of Christ, or from the very moment when he was born; but, whether they fell gradually into disesteem and ceased, as Christ and his gospel became known to mankind. And that they did so, is most certain from the concurrent testimonies of the fathers, which none can attempt to invalidate, without being prepared to give up the most respectable traditions and relations of every kind.

2dly, But did not Julian the Apostate actually consult these oracles? We answer in the negative. He had indeed recourse to magical operations, but it was because oracles had already ceased; for he bewailed the loss of them, and assigned for their cessation pitiful reasons, which St Cyril has vigorously refuted, adding, that Julian " never could have offered such, but from an unwillingness to acknowledge that, when the world had received the light of Christ, the dominion of the devil was at an end."

3dly, The Christian emperors do indeed condemn the superstition and idolatry of those who were still disposed to consult oracles; but the edicts of these princes do not prove that oracles actually existed in their times, any more than that they had ceased in consequence of their laws. It is certain that they were for the most part extinct before the conversion of Constantine.

4thly, Some Epicureans might make a jest of this superstition; but the Epicurean philosopher Celsus, in the second century, was disposed to cry up the excellency of several oracles, as appears at large from Origen's seventh book against him.

ORÆA, certain solemn sacrifices of fruits, which were offered in the four seasons of the year, in order to obtain mild and temperate weather. They were offered to the goddesses who presided over the seasons, attended upon the sun, and received divine worship at Athens.

ORAL, something delivered by word of mouth, without being committed to writing. In this sense we say oral law, oral tradition, oral communication, and the like.

ORAN, WARRAN, AURAN, or GUHARAN, a famous maritime city of Algiers, and the most westerly in the regency. It is built on the declivity and along the foot of a high mountain, which overlooks it from the north and northwest; and on this ridge are planted two castles, commanding the city on the one side and the port on the other. To the south and south-east there are two other castles, erected upon the same level with the lower part of the city, but separated from it by a deep winding valley, which serves as a natural trench on the south side. A rivulet flows through it, and passing afterwards under the walls of the city, affords a copious supply of water. At every opening of this valley a pleasing and varied prospect presents itself, of rocky precipices, orange plantations, and rills of water winding down the heights. Near the head of the rivulet just mentioned there is a fifth castle, which not only guards the *mattamores* dug under its walls, but serves as an important defence to the city. Yet strongly fortified as Oran is, both by nature and art, it has been repeatedly taken by the Spaniards, between whom and the Moors it was for centuries a subject of contention. It was taken by the former in the year 1509, but was recovered by the Moors in 1708. In the year 1732 the Spaniards retook it by surprise; the Bey, otherwise a valiant soldier, having been panic-struck on the first landing of the enemy, and, without shutting the gates, abandoned the city to their mercy. Oran was afterwards restored, and, along with other parts of Algiers, has recently fallen under the dominion of France. During the time that the Spaniards retained possession of Oran, they erected several beautiful churches, and other edifices, in the style of the Roman architecture, though of less strength and solidity. They have further imitated the Romans in carving upon the friezes and other parts several inscriptions in large characters, and in their own language. Shaw describes Oran as a fortified city, about a mile in circumference. The port called Mer-el-Quiver, corrupted from Mers-el-Kibeer, and answering to the ancient Portus Magnus, is formed by a neck of land, which runs out almost a furlong into the bay, and thereby secures it against the north and northwest winds. It is defended by a castle more remarkable for spaciousness and extent than for strength or beauty, though a part of it has been skilfully hewn out of the native rock. Oran has much declined of late years, as the occupation of the place by the French has induced the Arab population to leave it, although the former repaired some of the edifices, and converted an old mosque into an hospital. The inhabitants are estimated at about 4000. In the year 1790 this city was destroyed by an earthquake, and six thousand of its inhabitants were buried under the

[2] Numbers, xxiv. 14; xxxi. 16.

[3] 1 Kings, xxii. 19, &c.

ruins. Oran is situated in 35. 50. north, and longitude 0. 18. west.

ORANGE, an arrondissement of the department of the Vaucluse, in France, extending over 406 square miles. It comprehends seven cantons, divided into fifty communes, and contains 69,443 inhabitants. The capital, a city of the same name, is the seat of a bishop, and of some courts of law. It stands on a fruitful plain, watered by the river Meyne. It has large lofty houses, with narrow and crooked streets, a cathedral, a Protestant church, two hospitals, 1540 houses, and 8874 inhabitants, who make cotton, woollen, and silk goods, besides oil, wine, brandy, madder, and paper. It is in latitude 49. 4. N., and longitude 8. 8. east. It is remarkable as the district whence the house of Nassau derived its title as prince, which it has retained without the territory. The vicinity of the city exhibits many curious remains of Roman antiquity, especially a triumphal gate of three arches, half a mile from it, on a theatre, the walls of which are 108 feet in height. A part of this building has of late years been converted into a prison.

ORANGE River, a large river of Southern Africa, which derives its origin from the waters of the Snowy Mountains, in the district of Graaf-Reynet, nearly at the north-eastern extremity of the colony of the Cape of Good Hope. It is formed chiefly by two rivers, the Ky Gariep or Yellow River, and the Nu Gariep or Black River, which unite their waters in latitude 29. 4., upwards of five hundred miles due east from their mouth. The latter branch, flowing from the south-east, is called, higher up, the Cradock River, and receives the Sea-Cow River and some other streams from the Sneuwbergen. The Muddy or Alexander River, flowing also from the south-east, falls into the Yellow River above its confluence with the Nu Gariep. The former river, the Ky Gariep, comes from the north-east, and is formed by the union of the Vaal River with the Hart stream or Malalareen. After the junction of these two streams, the Orange River flows at first in a north-westerly course, but afterwards bends to almost due west, which bearing it maintains until it falls into the Atlantic in latitude 28. 30. north. In the eastern part of its course it forms the limit between the territory of the Hottentots and that of the Boshuanas; the country on the south presenting an entirely different character of animal and vegetable life from that on the north. In its westerly course this river winds its way through a desert of a clayey or swampy character; the sandstone rocks rising in perpendicular walls, which are often prolonged to a vast extent. The country retains the same aspect for a considerable space on both sides of the river; and the heat is here very great and oppressive. The course of the Orange River, including its windings, must considerably exceed one thousand miles.

Orange, Sea, in *Natural History*, a name given by Count Marsigli to a very remarkable species of marine substance, which he denominates a plant. It is tough and firm in its structure, and in many things resembles the common fucus; but instead of growing in the branched form which the generality of these substances assume, it is round and hollow, and in every respect resembles the shape of an orange. It has, by way of root, some exceedingly fine filaments, which fasten themselves to the rocks, or to shells, stones, or any thing else that comes in the way. From these there grows no pedicle; but the body of the orange, as it is called, is fastened by them to the rock, or other solid substance. The orange itself is usually about three or four inches in diameter; and whilst in the sea it is full of water, which it retains even when taken up. In this state it frequently weighs a pound and a half; but when the water is let out, and it is dried, it becomes a mere membrane, weighing scarcely any thing. It is best preserved by stuffing it with cotton as soon as the water is let out of it, and then hanging it up to dry. Its surface is irregular and rough, and its colour is a dusky green on the outside, and a clearer but somewhat bluish green within; and its thickness is about an eighth part of an inch. When viewed by the microscope, it is observed to be all over covered with small glandules, or rather composed of them; for they stand so thick one by another, as to leave no space between, and seem to constitute the whole substance; so that it appears very like the rough shagreen skin used to cover toys. These are indeed so many hollow ducts, through which the sea-water finds a passage into the globe formed by this skin, and by this means it is kept always full and distended. On cutting it with a pair of scissors, the water immediately runs out, and the skins collapse; but there is something extremely remarkable in this, for the whole substance, near the wounded place, is in motion, and seems as if alive, and sensible of the wound. The glandules are found full of water, resembling small transparent bottles; and what goes to the structure of the plant besides these, is an assemblage of a vast number of filaments, all of which are likewise hollow, being filled with a clear and transparent fluid.

ORATION, in *Rhetoric*, a speech or harangue, composed according to the rules of oratory, but spoken in public.

ORATOR, amongst the Romans, differed from a *patronus*. The latter was allowed only to plead causes on behalf of his clients; whereas the former might quit the forum, and ascend the rostra or tribunal, to harangue the senate or the people. The orators had rarely a profound knowledge of the law; but they were eloquent, and their style was generally correct and concise. They were employed in causes of importance, instead of the common patrons. Orators, in the violence of elocution, used the utmost animation of gesture, and even walked backwards and forwards with great heat and emotion. This it was which gave occasion to a witticism of Flavius Virginius, who asked one of these walking orators, *Quot millia passuum declamâsset?* "How many *miles* he had declaimed?" Similar to the Roman orators were the Grecian *rhetores*.

ORATORIO, in *Music*, a kind of sacred drama, in which the poetry is derived from some scriptural subject, and is set to music in recitatives, airs, duetts, trios, quartetts, &c. and choruses, accompanied by an orchestra, sometimes an organ, and introduced by an instrumental overture. The origin of the oratorio is not clearly established. Amongst the most remarkable oratorios of modern times is Haydn's "Creation."

ORATORY, the art of speaking well upon any subject, so as to persuade or convince. See Rhetoric.

Oratory, amongst the Roman Catholics, means a closet or small apartment near a bed-chamber, furnished with an altar and crucifix, for private devotions.

ORBE, a small city of Switzerland, in the canton of Vaud, on the river of the same name, across which there is a stone bridge. It contains 280 houses, with 1400 inhabitants. Anciently it was one of the largest of the cities in the country, and in the time of the Romans was, under the name of Urbigenum, the capital of Helvetia. In the middle ages the kings of the Franconian race had their palace here, and gave their splendid festivals; but in the Burgundian wars it suffered greatly, and declined so much as to become subject to the cantons of Berne and Friburg. It now contains some large houses. The inhabitants chiefly depend on agriculture, but have some trade with Geneva and Yverdun.

ORCHARD, a department in gardening, allotted entirely to the growth of standard fruit-trees, for furnishing a large supply of the most useful kinds of fruit. See Horticulture.

ORCHESTRA, in *Music*. See the article Music.

Ordeal.

ORCHESTRA, in the Grecian theatres, was that part of the *proscenium* or stage where the chorus used to dance. In the middle of it was placed the Λογειον or pulpit. The orchestra was semicircular, and surrounded with seats. In the Roman theatres it formed no part of the scene, but answered pretty nearly to the pit in our playhouses, being occupied with seats for senators, magistrates, vestals, and other persons of distinction. The actors never went down into the orchestra.

ORCHESTRINO, a modern musical instrument, so called by its inventor Poulleau. It was shaped like a piano-forte, had similar finger-keys, and its sounds were produced by the friction of a circular bow upon the strings. It imitated the tones of the violin, the viola, the violoncello, the viol d'amour, the double-bass, &c. The construction of the bow (of hair, &c.) is said to have been very curious and ingenious.

ORCHESTRION, a musical instrument invented by the Abbé Vogler about 1789. It was a kind of portable organ, about nine feet in height, breadth, and depth. Its power was that of an organ of sixteen feet pipe, and it had a mechanism to swell or to diminish all the sounds within its compass. Another instrument of the same name, invented in 1796, by Kunz, a Bohemian, consisted of a piano-forte, combined with some organ-stops.

ORCHIA LEX, instituted by Orchius the tribune, in the year of Rome 566. Its intention was to limit the number of guests who were to be admitted at an entertainment; and it is also provided that, during supper, which was the principal meal amongst the Romans, the doors of every house should be left open.

ORCHILLA, or HORCHILLA, a small cluster of islands in the West Indies, situated not far from the coast of South America, in latitude 12. north, and longitude 65. 20. west. The largest island, which bears the form of a crescent, is very hilly on the east and west capes, and here trees and verdure abound; but the other parts are low, and the soil, from its flatness, is barren, and productive of very few plants. There is little fresh water, no animals except goats and lizards, nor does it appear to contain any permanent population. On the south-west side the shore is nearly as perpendicular as a wall, and the water being very deep, vessels can approach close to it without danger. Navigation is extremely difficult amongst the Orchillas; for not only are the islands separated from each other by very narrow channels, but there are a number of currents, variable, violent, and dangerous.

ORCHON, a river of Chinese Tartary, which has its rise on the confines on the great desert of Shamo, and falls into the Selingha. Long. 106. 14. E. Lat. 50. N.

ORCUS, the god of the infernal regions, was the same with Pluto, and so called from the Greek word ὄρχος, signifying a tomb or sepulchre; or from ὅρκος, an oath sworn by the river Styx. The ancients gave this name to all the divinities of the infernal regions, even to Cerberus. There was a river of the same name in Thessaly, which took its rise in the marshes of the Styx, and the waters of which were so thick that they floated like oil upon the surface of the river Peneus, into which they discharged themselves. This probably suggested to the poets the idea of the infernal abodes, which they denominated Orcus. Orcus has been confounded with Charon. He had a temple at Rome.

ORDEAL, an ancient form of trial. It consisted in an appeal to the immediate interposition of divine power, being particularly distinguished by the appellation of *judicium Dei;* and was sometimes called *purgatio vulgaris,* to distinguish it from the canonical purgation, which was by the oath of the party. Two kinds of this trial were more common than the rest, at least in Europe; viz. fire-ordeal and water-ordeal. The former was confined to persons of high rank, the latter to the common people. Both these might be performed by deputy; but the principal was bound to answer for the success of the trial, the deputy only venturing some corporal pain, for hire, or perhaps for friendship.

That the purgation by ordeal, of some kind or other, is very ancient, admits not of a doubt; and that it was universal in the times of superstitious ignorance, seems to be equally certain. It appears even to have been known to the ancient Greeks; for, in the *Antigone* of Sophocles, a person suspected by Creon of a misdemeanour, declares himself ready "to handle hot iron and to walk over fire," in order to manifest his innocence, which, the scholiast tells us, was then an usual mode of purgation. And Grotius gives many instances of water-ordeal in Bithynia, Sardinia, and other places. It seems, however, to have been carried to a greater height amongst the Hindus than ever it had been in any nation or amongst any people, however rude or barbarous; for in a paper in the Asiatic Researches, communicated by Mr Hastings, we find that the trial by ordeal amongst that people is conducted in nine different ways: firstly, by the balance; secondly, by fire; thirdly, by water; fourthly, by poison; fifthly, by the *cosha,* or the water in which an idol has been washed; sixthly, by rice; seventhly, by boiling oil; eighthly, by red-hot iron; and ninthly, by images.

1. Ordeal by the balance is thus performed. The beam having been previously adjusted, the cord fixed, and both scales made perfectly equiponderant, the person accused and a pundit fast a whole day; then, after the accused has been bathed in sacred water, the *homa* or oblation presented to fire, and the deities worshipped, he is carefully weighed; and when he is taken out of the scale, the pundits prostrate themselves before it, pronounce a certain *mentra* or incantation, agreeably to the Shastras, and, having written the substance of the accusation upon a piece of paper, bind it on his head. Six minutes afterwards they place him again in the scale, and if he weigh more than before, he is held guilty; if less, innocent; if exactly the same, he must be weighed a third time, when, as it is written in the *Mitacshera,* there will certainly be a difference in his weight. Should the balance, though well fixed, break down, this would be considered as a proof of his guilt.

2. For the fire-ordeal, an excavation, nine hands in length, two spans in breadth, and one span in depth, is made in the ground, and filled with a fire of pippal-wood. Into this the person accused must walk barefooted; and, if his foot be unhurt, they hold him blameless; but if it be burned, he is held guilty.[1]

3. Water-ordeal is performed by causing the person

[1] In Europe, fire-ordeal was performed either by taking up in the hand, unhurt, a piece of red-hot iron, of one, two, or three pounds eight; or else by walking, barefooted and blindfold, over nine red-hot ploughshares, laid lengthwise at unequal distances; and if the arty escaped unhurt, he was adjudged innocent; but if it happened otherwise, as without collusion it usually did, he was then ondemned as guilty. However, by this latter method, Queen Emma, the mother of Edward the Confessor, is mentioned to have eared her character, when suspected of familiarity with Alwyn, bishop of Winchester. The first account which we have of Christians ppealing to the fire-ordeal, as a proof of their innocence, is that of Simplicius, bishop of Autun, who lived in the fourth century. This relate, as the story is related, before his promotion to the episcopal order, had married a wife, who loved him tenderly, and who, nwilling to quit him after his advancement, continued to sleep in the same chamber with him. The sanctity of Simplicius suffered, least in the voice of fame, by the constancy of his wife's affection; and it was rumoured about that the holy man, though a bishop, ersisted, in opposition to the ecclesiastical canons, to taste the sweets of matrimony; upon which his wife, in the presence of a great ncourse of people, took up a considerable quantity of burning coals, which she held in her clothes, and applied to her breasts, with-ut the least hurt to her person or her garments, as the legend says; and her example being followed by her husband with similar ccess, the credulous multitude admired the miracle, and proclaimed the innocence of the loving pair. A similar trick was played St Brice, in the fifth century. (Mosheim, *Ecclesiast. Hist.* vol. ii.)

accused to stand in a depth of water, either flowing or stagnant, sufficient to reach his navel; but care should be taken that no ravenous animal be in it, and that it be not moved by much air. A Brahmin is then directed to go into the water, holding a staff in his hand; and a soldier shoots three arrows upon dry ground from a bow of cane. A man is next despatched to bring the arrow which has been shot farthest; and, after he has taken it up, another is ordered to run from the edge of the water; at which instant the person accused is told to grasp the foot or the staff of the Brahmin, who stands near him in the water, and immediately to dive into it. He must remain under water till the two men who went to fetch the arrows have returned; for, if he raise his head or body above the surface before the arrows are brought back, his guilt is considered as fully proved. In the villages near Benares, it is the practice for the person who is to be tried by this kind of ordeal to stand in water up to his navel, and then, holding the foot of a Brahmin, to dive under it as long as a man can walk fifty paces very gently; if, before the man has walked thus far, the accused rise above the water, he is condemned; but if not, he is acquitted.

4. There are two sorts of trial by poison. Firstly, the pundits having performed their homa, and the person accused his ablution, two *rettis* and a half, or seven barley-corns of *vishanaga*, a poisonous root, or of *sauc'hya*, that is, white arsenic, are mixed in eight *mashas*, or sixty-four *rettis*, of clarified butter, which the accused must eat from the hand of a Brahmin. If the poison produce no visible effect, he is absolved; but if otherwise, he is condemned. Secondly, the hooded snake, called *nagga*, is thrown into a deep earthen pot, into which is dropped a ring, a seal, or a coin. This the person accused is ordered to take out with his hand; and, if the serpent bite him, he is pronounced guilty; but if not, he is declared innocent.

5. Trial by the cosha is as follows. The accused is made to drink three draughts of the water in which the images of the sun, of Devi, and other deities, have been washed for that purpose; and if, within fourteen days, he has any sickness or indisposition, his crime is considered as proved.

6. When several persons are suspected of theft, some dry rice is weighed with the sacred stone called *salgram*, or certain *slocas* are read over it; after which the suspected persons are severally ordered to chew a quantity of it. As soon as they have chewed it, they are to throw on it some leaves of *pippal*, or, if none be at hand, some *b'hurja patra*, or bark of a tree from Nepaul or Cashmere. The man from whose mouth the rice comes dry or stained with blood is held guilty; the rest are acquitted.

7. The ordeal by hot oil is exceedingly simple. When it is heated sufficiently, the accused thrusts his hand into it; and, if he be not burned, he is held innocent.

8. In the same manner they make an iron ball, or the head of a lance, red hot, and place it in the hands of the person accused, who, if it burn him not, is judged guiltless.

9. To perform the ordeal by *dharmach*, which is the name of the *sloca* appropriated to this mode of trial, either an image, named *dharma*, or the genius of justice, is made of silver, and another, called *adharma*, of clay or iron, both of which are thrown into a large earthen jar; and the accused having thrust his hand into it, is acquitted if he bring out the silver image, but condemned if he draw forth the iron. Or, one figure of a deity is painted on white cloth, and another on black; the first of which they name *dharma*, and the second *adharma*. These are severally rolled up in cow-dung, and thrown into a large jar, without having ever been shown to the accused, who must put his hand into the jar, and is acquitted or convicted according as he draws out the figure on white or on black cloth.

The superstitious weakness of mankind, when left to themselves, is astonishing. There is indeed nothing so absurd that they may not be made most firmly to believe, nothing so impious that they will not do. Nor can a more notorious instance of the truth of this assertion be possibly given than that of the trial by ordeal. The gross absurdity as well as impiety of pronouncing a man guilty unless he was cleared by a miracle, and of expecting that all the powers of nature should be suspended by an immediate interposition of Providence to save the innocent, when it was even presumptuously required, is self-evident. Yet the origin of this mode of trial may be traced to necessity as well as to superstition. At the time in which it originated in England, as well as in other countries of Europe, it was no easy matter for an innocent person, when accused of guilt, to get himself cleared by the then established mode of trial. It was therefore natural for superstition to fly to Heaven for those testimonies of innocence which the absurdity of human laws often prevented men from obtaining in the ordinary course of affairs. In this way, doubtless, did the trial by ordeal commence; and being thus begun by necessitous superstition, it was fostered by impious priestcraft and unjust power. During all the processes there was great room for collusion and deceit, and there can be no question but it was often practised; it could not, therefore, on any account, or in any case, be a sign of innocence or of guilt.

Besides the particular methods of trial which we have already mentioned, there were some few more common in European countries; as the judicial combat, the ordeal of the cross, and the ordeal of the corsned.

The judicial combat was well suited to the genius and spirit of fierce and warlike nations, and, as we might reasonably expect, formed one of the most ancient and universal modes of trial. We know that it was exceedingly common in Germany in very remote ages. It was also used in some countries on the Continent at a pretty early period; but it is not mentioned in any of the Anglo-Saxon laws, and it does not appear to have been much used in England until after the Conquest. It was so much the custom in the middle ages of Christianity to respect the cross even to superstition, that it would indeed have been wonderful if the same ignorant bigotry had not converted it into an ordeal; and accordingly we find it used for this purpose in so many different ways as almost to preclude description. In criminal trials, the judgment of the cross was commonly conducted in this manner. When the prisoner had declared his innocence upon oath, and appealed to the judgment of the cross, two sticks were prepared exactly like one another; the figure of the cross was cut on one of these sticks, and nothing on the other; each of them was then wrapped up in a quantity of fine white wool, and laid on the altar, or on the relics of the saints; after which a solemn prayer was offered up to God, that he would be pleased to discover, by evident signs, whether the prisoner was innocent or guilty. These solemnities being finished, a priest approached the altar, and took up one of the sticks, which was uncovered with much anxiety. If it was the stick marked with the cross, the prisoner was pronounced innocent; but if it was the other, he was declared guilty. When the judgment of the cross was appealed to in civil causes, the trial was usually conducted in this manner. The judges, parties, and all concerned, being assembled in a church, each of the parties chose a priest, the youngest and stoutest whom he could find, to be his representative in the trial. These representatives were then placed one on each side of some famous crucifix; and, at a signal given, they both at once stretched their arms at full length, so as to form a cross with their body. In this painful posture they continued to stand whilst divine service was performing; and the party whose representative dropped his arms first lost his cause.

The corsned, or the consecrated bread and cheese, was the ordeal to which the clergy commonly appealed when they were accused of any crimes; and in this they acted a very prudent part, as it was attended with no danger or inconvenience. This ordeal was performed in this manner. A piece of barley bread and a piece of cheese were laid upon the altar, over which a priest pronounced certain conjurations, and prayed with great fervency, that if the person accused was guilty, God would send his angel Gabriel to stop his throat, that he might not be able to swallow that bread and cheese. These prayers being ended, the culprit approached the altar, took up the bread and cheese, and began to eat it. If he swallowed freely, he was declared innocent; but if it stuck in his throat, and he could not swallow, which we may presume seldom or never happened, he was pronounced guilty.

Besides these, there were a variety of other ordeals practised in Christian countries, many of which retain the same names which were used amongst Pagans, and differ only as to the mode in which they were performed. In all nations of Christians where these trials were used, we find the clergy engaged in them. Indeed, in England, as late as the time of King John, we find grants to the bishops and clergy to use the *judicium ferri, aquæ, et ignis;* and, both in England and Sweden, the clergy presided at this trial, and it was only performed in the churches, or in other consecrated ground. "Non defuit illis operæ et laboris pretium," says Stiernhook; "semper enim ab ejusmodi judicio aliquid lucri sacerdotibus obveniebat." But, to give the canon law its due praise, we find it at a very early period declaring against trial by ordeal, or *vulgaris purgatio,* as being the work of the devil, "cum sit contra præceptum Domini, *Non tentabis Dominum Deum tuum.*" Upon this authority, though the canons themselves were of no validity in England, it was thought proper (as had been done in Denmark above a century before) to disuse and abolish this trial entirely in our courts of justice, by an act of parliament 3 Henry III. according to Sir Edward Coke, or rather by an order of the king in council.

It may still perhaps be a postulate with some in what manner the effects of these trials were evaded, and how it was possible to appear to do that which we know could not be really done without material injury to the persons concerned. On this subject Dr Henry observes, in reference to the ordeals in ancient Britain, that, if we suppose few or none escaped conviction who exposed themselves to those fiery trials, we shall be very much mistaken. "For the histories of those times contain innumerable examples of persons plunging their naked arms into boiling water, handling red-hot balls of iron, and walking upon burning ploughshares, without receiving the least injury. Many learned men have been much puzzled to account for this, and disposed to think that Providence graciously interposed, in a miraculous manner, for the preservation of injured innocence. But if we examine every circumstance of those fiery ordeals with due attention, we shall see sufficient reason to suspect that the whole was a gross imposition on the credulity of mankind. The accused person was committed wholly to the priest who was to perform the ceremony, three days before the trial, in which he had time enough to bargain with him for his deliverance, and give him instructions how to act his part. On the day of trial, no person was permitted to enter the church but the priest and the accused till after the iron was heated, when twelve friends of the accuser, and twelve of the accused, and no more, were admitted, and ranged along the wall on each side of the church, at a respectful distance. After the iron was taken out of the fire, several prayers were said; the accused drank a cup of holy water, and sprinkled his hand with it, which might take a considerable time if the priest was indulgent. The space of nine feet was measured by the accused himself with his own feet, and he would probably give but scanty measure. He was obliged only to touch one of the marks with the toe of his right foot, and allowed to stretch the other foot as far towards the other mark as he could, so that the conveyance was almost instantaneous. His hand was not immediately examined, but wrapped in a cloth prepared for that purpose three days. May we not, then, from all these precautions, suspect that those priests were in possession of some secret that secured the hand from the impressions of such a momentary touch of hot iron, or removed all appearance of these impressions in three days; and that they made use of this secret whenever they saw reason? What greatly strengthens these suspicions is, that we meet with no example of any champion of the church who suffered the least injury from the touch of hot iron in this ordeal; but when any one was so fool-hardy as to appeal to it, or to that of hot water, with a view to deprive the church of any of her possessions, he never failed to burn his fingers, and lose his cause."

To this we may add what the learned Beckmann[1] has stated concerning the imposition which was probably practised in the ordeal by fire. "I am not acquainted with every thing that concerns the trial by ordeal, when persons accused were obliged to prove their innocence by holding in their hands red-hot iron; but I am almost convinced that this was also a juggling trick of the popes, which they employed as might best suit their views. It is well known that this mode of exculpation was allowed only to weak persons, who were unfit to wield arms, and particularly to monks and ecclesiastics, to whom, for the sake of their security, that by single combat was forbidden. The trial itself took place in the church, entirely under the inspection of the clergy; mass was celebrated at the same time; the defendant and the iron were consecrated, by being sprinkled with holy water; the clergy made the iron hot themselves; and they used all these preparatives, as jugglers do many motions, only to divert the attention of the spectators. It was necessary that the accused person should remain at least three days and three nights under their immediate care, and continue as long after. They covered his hands both before and after the proof, sealed and unsealed the covering; the former, as they pretended, to prevent the hands from being prepared any how by art; the latter, to see if they were burned.

"Some artificial preparation was therefore known, else no precautions would have been necessary. It is highly probable, that during the first three days the preventive was applied to those persons whom they wished to appear innocent; and that the three days after the trial were requisite to let the hands resume their natural state. The sacred sealing secured them from the examination of presumptuous unbelievers; for, to determine whether the hands were burned, the last three days were certainly not wanted. When the ordeal was abolished, and this art rendered useless, the clergy no longer kept it a secret. In the thirteenth century, an account of it was published by Albertus Magnus, a Dominican monk.[2] If his receipt be

[1] Vol. iii. 297.

[2] In his work *De Mirabilibus Mundi*, at the end of his book *De Secretis Mulierum*, Amsterdam, 1702, 12mo, p. 100. "Experimentum mirabile quod facit hominem ire in ignem sine læsione, vel portare ignem vel ferrum ignitum sine læsione in manu. Recipe succum bismalvæ, et albumen ovi, et semen psylli et calcem, et pulveriza, et confice cum illo albumine ovi succum raphani; commisce; ex hac confectione illineas corpus tuum vel manum, et dimitte siccari, et postea iterum illineas, et post hoc poteris audacter sustinere ignem sine nocumento."

Order.

genuine, it seems to have consisted rather in covering the hands with a kind of paste than in hardening them. The sap of the *althæa* (marshmallow), the slimy seeds of the flea-bane, which is still used for stiffening by the hat-makers and silk-weavers, together with the white of an egg, were employed to make the paste adhere. And by these means the hands were as safe as if they had been secured by gloves.

"The use of this juggling trick is very old, and may be traced back to a Pagan origin. In the *Antigone* of Sophocles, the guards placed over the body of Polynices, which had been buried contrary to the orders of Creon, offered, in order to prove their innocence, to submit to any trial. We will, said they, take up red-hot iron in our hands, or walk through fire."

ORDER, in *Architecture*, is a system of the several members, ornaments, and proportions of columns and pilasters; or a regular arrangement of the projecting parts of a building, especially the column, so as to form one beautiful whole. See ARCHITECTURE.

ORDER is also used to signify a division or class of any thing. Thus the tribe of animals called *birds* is subdivided into orders.

ORDER, in *Rhetoric*, is the placing of each word and member of a sentence in such a manner as will most contribute to the force, beauty, or evidence of the whole; according to the genius and custom of different languages. With regard to order, we may observe in general, that, in English, the nearer we keep to the natural or grammatical order, so much the better; but in Latin we are to follow the use of the best writers, a joint regard being always had to the judgment of the ear, and the perspicuity of the sense, in both languages.

ORDER is also used to signify a class or division of the members of a state, with regard to assemblies, precedence, levees, and other circumstances.

ORDERS, by way of eminence, or *Holy ORDERS*, denote a character peculiar to ecclesiastics, by which they are set apart for the holy ministry.

In no reformed church are there more than three orders, namely, bishops, priests, and deacons. In the Roman Catholic church there are seven, exclusive of the episcopate, all of which the council of Trent enjoins to be received and believed, on pain of anathema. They are distinguished into petty, or secular orders; and major, or sacred orders.

ORDERS, the petty, or minor, are four; those of door-keeper, exorcist, reader, and acolyte. Persons in petty orders may marry without any dispensation. In effect, the petty orders are looked on as little other than formalities, and as degrees necessary to arrive at the higher orders. The Greeks disavow these petty orders, and pass immediately to the subdeaconate; and the reformed churches to the deaconate. Their rise Fleury dates in the time of the Emperor Justinian. There is no call nor benefice required for the four petty orders; and even a bastard may enjoy them without any dispensation, nor does a second marriage disqualify.

ORDERS, sacred, or major, are, as has already been observed, three, viz. those of deacon, priest, and bishop. The council of Trent, reviving the ancient discipline, forbids any person being admitted to the major orders, unless he be in peaceable possession of a benefice sufficient for a decent subsistence, and allows no ordinations on patrimonies or pensions, except where the bishop judges it for the service of the church. A person is said to be promoted to orders *per saltum*, when he has not before passed the inferior orders. The council of Constantinople forbids any bishop being ordained without passing all the degrees; yet ecclesiastical history furnishes us with instances of bishops consecrated without having passed the order of priesthood; and Panormus still thinks that such an ordination is valid.

Military ORDERS are companies of knights, instituted by kings and princes, either for defence of the faith, or to confer marks of honour and grant distinctions to meritorious subjects.

Religious ORDERS are congregations or societies of monastics, living under the same superior, in the same manner, and wearing the same habit. Religious orders may be reduced to five kinds, namely, monks, canons, knights, mendicants, and regular clerks. Father Mabillon shows, that till the ninth century, almost all the monasteries in Europe followed the rule of St Benedict; that the distinction of orders did not commence till after the reunion of several monasteries into one congregation; that St Odo, abbot of Cluny, first began this reunion, bringing several houses under the dependence of Cluny; and that, a little afterwards, in the eleventh century, the Camaldulians arose, then the congregation of Vallombrosa, the Cistercians, Carthusians, Augustines, and at last, in the thirteenth century, the Mendicants. He adds, that Lupus Servatus, abbot of Terrières, in the ninth century, is the first who seems to distinguish the order of St Benedict from the rest, and to speak of it as a particular order.

White ORDER denoted the order of regular canons of St Augustin.

Black ORDER denoted the order of Benedictines.

These names were at first given to the two orders in question, from the colour of their habit; but were disused after the institution of several other orders, who adopted the same colours.

Gray ORDER was the ancient name of the Cistercians; but, since the change of the habit, the name is no longer applicable.

ORDERS, religious military, are those instituted in defence of the faith, and privileged to say mass; but who are prohibited marriage, and subjected to other restraints.

Of this kind were the knights of Malta, or of St John of Jerusalem, the Knights Templars, the knights of Calatrava, the knights of St Lazarus, the Teutonic knights, and various others.

ORDINAL NUMBERS, those which express order, as 1st, 2d, 3d, 4th, and so on.

ORDINANCE, or ORDONNANCE, means a law, statute, or command of a sovereign or superior. Thus the acts of parliament are sometimes termed "ordinances of parliament," as in the parliament rolls; although in some cases we find a difference made between the two, ordinances being only temporary things, by way of prohibition, and capable of being altered by the commons alone, whereas an act is a perpetual law, and cannot be altered except by king, lords, and commons.

Coke asserts, that an ordinance of parliament differs from an act, as the latter can only be made by the three-fold consent of the estates; whereas the former may be made by one or two of the estates.

In the French jurisprudence, ordonnances are such laws as are established by the king's authority alone.

ORDINARY, in general, signifies common, usual. Thus, an ambassador, or envoy, in ordinary, is one sent to reside statedly, and for a number of years, at the court of some foreign prince or state, in order to keep up a good understanding, and watch over the interest of his own nation.

ORDINARY, in nautical language, denotes the establishment of the persons employed by government to take charge of the ships of war which are laid up in the several harbours adjacent to the royal dock-yards. These are principally composed of the warrant officers of the said ships, as the gunner, boatswain, carpenter, deputy-purser, and cook, with three servants. There is, besides, enrolled in the list of the ordinary, a crew of labourers, who pass from ship to ship occasionally, to pump, moor, remove, or clean them, whenever it is necessary.

The term *ordinary* is also applied sometimes to the ships themselves; and it is likewise used to distinguish the inferior sailors from the most expert and diligent. The latter are rated *able* on the navy books, and have higher pay than those who are rated as *ordinary.*

Ordinary *of Assizes* and *Sessions*, was a deputy of the bishop of the diocese, anciently appointed to give malefactors their neck-verses, and judge whether they read or not; to perform divine service for them, and assist in preparing them for death.

Ordinary *of Newgate*, is one who attends in ordinary upon the condemned malefactors in that prison, to prepare them for death, and who records the conduct and behaviour of such persons.

ORDINATES, in *Geometry* and *Conics*, are lines drawn from any point of the circumference of an ellipsis, or other conic section, perpendicularly across the axis, to the other side.

ORDINATION, the act of conferring holy orders, or of initiating a person into the priesthood, by prayer and the imposition of hands.

Ordination has always been esteemed a principal prerogative of bishops, and they still retain the function as a mark of spiritual sovereignty in their diocese. The ordination of bishops is properly called *consecration.* Ordination is one of the sacraments of the church of Rome. In the established church of Scotland, where there are no bishops, the power of ordination is lodged in the presbytery; and by the Independents, in the suffrage of the people.

ORDNANCE, a general name for all sorts of great guns used in war.

Master-General of the Ordnance is deemed the principal officer in the civil branch of the ordnance; yet he is always chosen from amongst the first generals in his majesty's service.

Lieutenant-General of the Ordnance receives all orders and warrants signed by the master-general, and from the other principal officers, and sees them duly executed; issues orders as the occasions of the state require; and gives directions for discharging the artillery when required at coronations, birth-days, signal victories, and other solemn occasions.

Surveyor-General of the Ordnance inspects the stores and provisions of war in the custody of the storekeeper, and sees that they are ranged and placed in such order as is most proper for their preservation.

Clerk of the Ordnance, an officer whose function is to record all orders and instructions given for the government of the office; all patents and grants; and the names of all officers, clerks, artificers, gunners, labourers, and the like.

Storekeeper of the Ordnance takes into his custody all his majesty's ordnance, munitions, and stores belonging thereto, and indents and puts them in legal security, after they have been surveyed by the surveyor-general, any part of which he must not deliver without a warrant signed by the proper officers.

Clerk of the Deliveries of the Ordnance draws all orders for delivery of any stores, and sees them duly executed.

Treasurer and Paymaster of the Ordnance receives and pays all moneys, both salaries and debentures, in and belonging to this office.

ORDONNANCE, in architecture, is the composition of a building, and the disposition of its parts, both with regard to the whole and to one another; or, as Mr Evelyn expresses it, determining the measure of what is assigned to the several apartments. Thus ordonnance is the judicious contrivance of the plan or mould; as when the court, hall, or other building or apartment, is neither too large nor too small, and that the court affords convenient light to the apartments around it, the hall is of a fit capacity to receive company, and the bed-chambers of a proper size. When these divisions are either too great or too small with respect to the whole, as where there is a large court to a little house, or a small hall to a magnificent palace, the fault is in the ordonnance.

Ordonnance, in *Painting*, is used for the disposition of the parts of a picture, either with regard to the whole piece or to the several parts, as the groups, masses, contrasts, and so forth.

ORE, a mineral body, partly or entirely composed of some metallic substance, in the natural state in which it exists in the earth. Metallic substances are found either native, that is, pure, and uncombined with other substances, or alloyed with other metals, or combined with oxygen or sulphur, or with acids. Thus it appears that metals exist in ores in four different states; in the metallic state, when they are either pure, or combined with each other, as in the state of alloy; in the state of an oxide; combined with sulphur in the state of sulphuret; and, with acids, forming salts.

OREEHOUA, one of the smaller Sandwich Islands, which is a single high hummock, and is only separated from Onehow by a channel about a mile in width. The population is 4000.

OREGON Territory, a vast extent of country belonging to the United States of North America, and situated to the west of the Rocky Mountains. It is bounded on the north by the British and Russian possessions, the limits of neither power having been very clearly fixed. On the west it is bounded by the Pacific; on the south by Mexico; and on the east by the stupendous ridges of the Rocky Mountains, situated in the territories of Arkansas and Missouri. It may be assumed as stretching between the forty-first and fifty-fourth parallels of north latitude, and the thirty-fourth and forty-eighth meridians of west longitude. The waters which rise on the western declivities of the gigantic mountain chain bounding Oregon on the east, flow into the Columbia, the Multnomah, and the lake Buene-ventura. In general the elevated summits of the Rocky Mountains rise above the line of perpetual congelation. Beyond the mountains the country descends by regular belts, in the form of immense terraces, or descending plains, disposed regularly, the one below the other. Beyond the first plain, and between the Rocky Mountains and the Pacific, is another extensive and high chain of mountains, in which are the great falls of the Columbia; still farther to the west, running parallel with the coast, and at the distance of one hundred and fifty miles, is the third and last chain. The peaks of all these mountain ridges are covered with perpetual snow. The loftiest of them have been named Mount Baker, Mount Regnier, Mount St Helens, Mount Hood, and Mount Jefferson.

The Columbia and its branches are the only rivers which have been explored to any extent in the region of Oregon. This noble river, sometimes named after the territory, has its head waters near those of the Missouri, and it collects innumerable tributary streams throughout a great extent along the western ridges of the Rocky Mountains. Immediately after it emerges from these, its current becomes broad and deep, and having received Clarke's and Lewis' Rivers, which flow into it on the south-east side, its breadth is enlarged to nine hundred and sixty yards. It there takes a great bend to the south, and penetrates the second mountain barrier. One hundred and thirty-six miles lower down are the great falls, where the river descends fifty-seven feet in one rapid; but none of the cataracts singly are above twenty feet. Below these falls it winds first to the north-west, and then to the south-west, and intersects the third chain of mountains, where it is again compressed to one hundred and fifty yards in breadth. Below this rapid, which is distant one hundred and eighty miles from the Pacific, it meets the tide, and from this point it has a broad estuary to the sea. Sixty miles below the rapids, the Wallamat or Multnomah, a large tributary, flows in from the north-east; and this river, together with those of Clarke and Lewis, constitute the three great tributary streams of the Columbia. Vessels of three hundred tons may reach the Multnomah, and large sloops may ascend as high as the tide. Above the rapids the navigation is good for sixty-five miles, when it is interrupted by the long narrows; and higher up it is also interrupted by falls, which renders about five miles of portage necessary to obviate these obstructions to navigation. The river at the narrows, for upwards of three miles, is compressed into a strait, not exceeding sixty or seventy yards in breadth, the whole of which is a succession of boiling whirlpools. The Columbia flows into the Pacific Ocean in latitude 46. 19. north, and longitude 123. 54. west; and although its main sources are estimated at only eight degrees of latitude from this, yet if we take into calculation its serpentine windings, its course cannot be less than fifteen hundred miles. The mouth of this great river is upwards of four miles wide, and, to the distance of thirty or forty miles from its entrance into the sea, it is, properly speaking, a mere estuary, indented by deep bays, so as to vary from three to seven miles in width. It is rendered extremely intricate and dangerous by shoals reaching nearly from shore to shore, on which at times the winds and currents produce foaming and tumultuous breakers. The river proper, however, is only about half a mile wide at its confluence with the sea, being narrowed by the contracting shores of the estuary. The entrance from the Pacific is bounded on the southern side by a flat sandy neck of land, stretching into the ocean, and commonly called Point Adams. The opposite or northern side is Cape Disappointment, a kind of peninsula, terminating in a steep knoll or promontory, crowned with a forest of pine-trees, and connected with the mainland by a low and narrow neck. The Columbia River is, for a considerable distance, seldom less than a mile in breadth; in some places it is from two to five miles wide, and in others it forms lakes of very considerable magnitude. The shores are generally bold and thickly wooded. Pine in all its varieties predominates, and is mixed with white oak, ash, beech, poplar, alder, crab, and cotton wood, with an undergrowth of briars and other shrubs. Up to the rapids the river is covered with numerous islands, from one to three miles in length, some of which present fine meadows, and others are well wooded. Sand banks also prevail, and these, being so large and high as to be laid bare at low water, materially obstruct the navigation of the river. In the neighbourhood of these the shores are generally low, and present some fine flat "bottoms" of meadow ground, bordered by a profusion of blackberry and other wild-fruit shrubs; in the deep and narrow parts of the channel the shores are bolder. The pine-tree declines considerably above the rapids, and is much more equally mixed with other trees, amongst which the hazel occasionally predominates. But in regard to size, the pine and the cedar are as gigantic at the very source of the Columbia as they are on the shores of the Pacific. The Columbia and its tributaries abound with the finest salmon, which seem in fact to constitute the principal article of food of the savages who inhabit the country to the west of the Rocky Mountains. Seals and other aquatic animals are likewise abundant in this river, and the skins, which are exported to China, constitute the chief article of trade. A number of the head streams of the Missouri interlock with the waters of this river, as Wisdom River with Clarke's of the Columbia; and Jefferson of the Missouri with Lewis's of the Columbia. Clarke's River has a course of between two and three hundred miles before it unites with the Columbia. Lewis's River is also a large and long tributary, receiving in its course the North Fork and Kooskooskee, and, after winding six hundred miles, it joins the Columbia by a mouth upwards of six hundred yards in width. The current is very rapid. Its waters are deep, of a white colour, and slightly tepid, in which respect Lewis River forms a marked contrast with the Columbia, the waters of which are quite clear and cool. The latter river at this place is upwards of one thousand yards wide, and the current descends at an even rate of about four miles an hour. The two most important rivers which join the Columbia below the rapids are, the Multnomah, which has been already mentioned, and the Coweliskee. The general course of the former is a little to the eastward of south. It runs through a low, well-wooded country, for upwards of sixty miles, when the navigation is interrupted by a considerable fall, above which the channel contracts, and the banks become higher and less wooded. The climate on the shores of this river is remarkably mild, and not so moist as it is on the coast. It possesses a rich and luxuriant soil, which yields an abundance of fruits and roots; and amongst other herbs the tobacco plant has been discovered, and found to be of excellent quality. The Indians here are of a pacific character. There are no noxious reptiles, and beaver, deer, and elk are plentiful. Indeed it is anticipated, that when Oregon shall become generally colonized, the country about the Wallamat will be rendered one of the most delightful districts to the westward of the Rocky Mountains. Little is known of the Coweliskee. It enters the Columbia from the northward, about half a day's journey below the Wallamat. Its banks are high and thickly wooded, but its current is much interrupted by rapids.

Little information has been obtained regarding the geological features of this vast expanse of country; but it is presumed that the western declivities of these mountains are of primitive formation. The territory must have an abrupt slope towards the Pacific, as it descends as much in six hundred miles to the west, as it does in one thousand five hundred miles to the east. The summits of the mountain ranges, being rugged rocks, the only covering of which is snow, that remains during the greater part of the year, are necessarily sterile; but these rocky chains embosom and shelter valleys of considerable fertility. The timber which clothes the mountains consists of pine, spruce, fir, and the other terebinthines. The terrace plains below have in general a fine soil, but they are very scantily furnished with timber, except on the banks of the rivers. The prairies are covered with grass and a profusion of beautiful flowers, the same as on the eastern sides of the mountains. Amongst the prairie plants are found various species of edible roots, which are used by the savages, in addition to the immense quantities of salmon, which constitute their staple article of food. Wild sage is not only a most abundant herb, but it grows to so large a size that it is used as the chief article of fuel on these extensive plains. Deep and thick forests of such evergreens as pine and hemlock stretch along the shore, and extend a considerable way into the interior; and altogether it appears that the region which lies between the Rocky Mountains and the Pacific Ocean possesses in many parts a fertile soil, besides enjoying an agreeable climate. Its southern border, where it joins with Mexico, is indeed remarkably mild. In the year 1805 this region was explored by order of the American government; and from the tables which were drawn up by Lewis and Clarke, the persons employed on that service, a pretty correct idea may be formed of the meteorology, and consequently of the climate, of the country in question. From September it gradually became colder till the end of January, after which the rigour of the winter abated, and by the end of

February it was "quite warm." By the middle of March plants appeared above ground, and put forth their leaves; and on the 30th of that month, "grass was sixteen inches high in river bottoms." It is not, however, till the end of May that snow disappears from the high plains; and about the beginning of June the river Columbia is at its greatest height, being swelled by the melting of the snow on the mountains. Strawberries are ripe at the end of this month, and July and August appear to be the season when fruits and flowers arrive at full perfection. From other and more recent authorities we learn that the summer is reckoned temperate, the thermometer never rising above eighty degrees. Westerly winds prevail during the spring and early part of summer, and they are succeeded by fresh breezes from the north-west. In the month of October the southerly winds set in, bringing with them frequent rain. The rainy season, which commences in this month, continues, with little intermission, till April; and although the winters, as we have already observed, are mild, the mercury in the thermometer seldom sinking below the freezing point, yet the tempests of wind and rain are terrible. The sun is said to be sometimes obscured for weeks, the brooks swell into roaring torrents, and the country is threatened with a deluge.

The foregoing observations regarding the climate, soil, and productions of Oregon, apply chiefly to that part of the country which lies between the rapids and the Pacific Ocean. Mr Ross Cox, who spent several years in this region, informs us, that from the falls to the land of the Spokans, a distance of about five hundred miles, the summers are excessively hot, and the winters intensely cold, yet the climate is withal remarkably healthy, and, during these seasons, subject to but little variation. The soil is unproductive, consisting chiefly of a light yellowish sandy clay. The plains are covered with a short kind of grass, mixed with prickly pears, wormwood, and tufts of long, coarse grass, from three to five feet in height. Patches of clover are here and there visible, and in their vicinity the chappallel and the camas or quamash roots are found. Wild onions grow in considerable quantities along the banks of the river above the falls. Cotton wood, small willow, sumac, furze, and sarsaparilla, are also occasionally found; but from the falls to Spokan River, none of the larger trees are met with. The principal animals are horses, small deer, prairie wolves, red foxes, badgers, polecats, hares, and dogs. Otters are sometimes seen; but the great staple animal of the American trapper, the beaver, is a stranger to this particular district, whilst in other parts of the country it is frequently found. The Indians affirm that buffaloes were formerly numerous, but, together with the elk and the sheep, they have long since deserted the plains. No rattle-snakes are seen below the falls; but at a short distance above them they make their appearance, and are in some parts very numerous, as are also horned lizards and grasshoppers. Within the region of the Rocky Mountains vegetation on the Columbia is rich and luxuriant, including all the varieties, from a profuse growth of blackberry and wild cherry, to the stately pine and majestic cedar. On the eastern side of the mountains, the reverse of this is observed, vegetation being dwarfish and stunted. The difference is supposed to arise from the great humidity of the atmosphere on the Columbia. There, westerly and south-westerly winds prevail during eight months of the year, and are loaded with exhalations from the Pacific. Such of the clouds as are not arrested by the high lands on the coast, are stopped in their progress eastward by the lofty chain of the Rocky Mountains, and thus serve to keep the climate perpetually moist.

In the year 1811, a settlement was formed by American citizens at the mouth of the Columbia, and called Astoria, after Mr Astor, who conceived the idea of forming an extensive fur dépôt in this part of America. Astoria was taken by the British in 1813, and by them the name of the place was changed to that of Fort George. The soil and productions of this portion of the Oregon territory are thus described by Mr Ross Cox. "The soil in the valleys consists of a bed of rich black mould, about six inches in depth, which covers a stratum of gray earth, extremely cold. The latter lies on a layer of large gravelly sand; and under all is a bed of hard flinty stones. On the high grounds, under a thin covering of black mould, are found good quarry stones, well adapted for building. There is a bank of white earth, resembling chalk, to the southward of Point Adams; and farther on in the same direction, the Indians find red, green, and yellow earths, and a species of heavy shining clay resembling lead-mine. No limestone is found in the neighbourhood." In June there are, amongst other wild fruits, small white strawberries, of a sweet flavour; and these are followed by red and amber raspberries, which grow upon bushes from ten to fifteen feet in height. During the three months which follow, there are obtained considerable quantities of blueberries, blackberries, wild cherries, gooseberries, wild pears, and a species of bitter crab-apple. There is a shrub of a peculiar description, which yields a fruit much esteemed by the natives. The country likewise abounds in various nutritive roots, amongst which is a kind resembling young onions, collected by the Indians in great quantities, which, after being dried and pulverized, are made into loaves, and laid up for seasons of scarcity. The principal quadrupeds are the elk, the red deer, the black-tailed deer; the black, brown, and grizzly bear, the last of which is extremely ferocious; the wolf, lynx, panther, tiger-cat, wild cat, marmot, fox, beaver, land-otter, sea-otter, musk-rat, wood-rat, and the horse. White bears are occasionally killed on the coast to the northward of the Columbia, but they are scarce. The most remarkable of the feathered tribes are the black, brown, and nun eagle, the hawk, pelican, cormorant, swan, heron, crane, bustard, gray and white goose, various species of wild duck, and other water-game. In some parts, the humming-bird and bee, in great numbers, banquet during the summer months amongst the wild flowers and aromatic herbs. The trees most common in the neighbourhood of Astoria are the cedar, spruce, pine, alder, and some others equally valuable. The cedars are from twenty to thirty feet in circumference, and proportionally high. The alders also are extremely large; and ash and oak, the former of a tolerable size, are found a few leagues above the fort.

The rivers and the lakes are most abundantly furnished with fish of various kinds. In the spring months they swarm with immense quantities of small fish resembling pilchards, which are smoke-dried, and form an important article of barter with the upper Indians for roots. Prime sturgeon, which attains an enormous size, abound in the months of August and September; but the grand staple is salmon, the chief fishing of which is at the "long narrows," already mentioned, where the river, compressed into a channel from fifty to one hundred feet in breadth, boils and roars with great fury for a distance of three miles. In the spring of the year, when the water is high, the salmon ascend the river in incredible numbers. As they pass through this narrow strait, the Indians, standing upon the rocks, or on the end of wooden stages projecting from the banks, scoop them up with small nets distended on hoops, and attached to long handles, and cast them ashore. They are then cured and packed in a peculiar manner. After being disembowelled, they are exposed to the sun on scaffolds erected on the river-banks. When sufficiently dry, they are pounded fine between two stones, pressed into the smallest compass, and packed in baskets or bales of grass matting, about two feet in length and one in diameter, lined with the cured skin of a salmon. Packages are then made, each containing twelve of these bales, and being well wrapped up and secured, they are placed in dry situations, and again covered with matting. Each of these packages contains from ninety to a hundred pounds of dried fish, which in this state will keep sound for several years. At the head of the long narrows the Indians had some years ago, and have still, it is presumed, their principal trading mart or emporium. Here the salmon caught in the neighbouring rapids are "warehoused," to await customers. Hither the tribes from the mouth of the Columbia repair with the fish of the sea-coast, the roots, berries, and especially the wappatoo, gathered in the lower parts of the river, together with goods and trinkets obtained from the ships which visit the coast, or from the colonists. Hither also the tribes from the Rocky Mountains bring down horses, bear grass, quamash, and other commodities of the interior. The trade is of course pursued on the primitive principle of barter, the merchant fisherman acting as middleman or factor.

Although only a comparatively small portion of Oregon, and that chiefly situated on the banks of the great river, has been described, the greater part of the territory being still an unexplored wilderness, yet from this partial account we are induced to form a favourable opinion of the country. Wood appears to abound on the banks of the rivers, but many of the immense prairies of which the interior principally consists are nearly destitute of it, being chiefly covered with a coarse grass, and a prodigious growth of prickly pear, and other shrubs. Occasionally, however, there intervene bright green patches intermixed with wild flowers, and gently rising eminences, partially covered with clumps of small trees, which give an agreeable variety to the face of the country. Lewis and Clarke give a very pleasing account of what they term the great Columbian valley. It is sixty miles in width, and extends far to the south-south-east, between parallel ridges of mountains, which bound it on the east and west. Through the centre of this valley flows the Wallamat, which has already been described as traversing for several hundred miles a still unviolated wilderness. The sheltered situation of this immense valley has an obvious effect upon the climate, as might be expected. It is represented as a region of great beauty and luxuriance, with lakes, and pools, and green meadows, shaded by noble groves. Various Indian tribes are said to reside in this valley, and all along the banks of the Wallamat. There is another place called Oakinagan, of which Mr Ross Cox gives a very flattering description. It is a point of land three miles in length by two in breadth, formed by the confluence of the river Oakinagan with the Columbia. This small spot is enclosed at the upper end by a chain of hills, within which the rattlesnakes never intrude. The climate here is highly salubrious, the soil is fertile, producing immense quantities of sarsaparilla; the horses are abundant, and ample facilities exist for water-carriage. The native Indians who inhabit the peninsula are an honest, quiet, inoffensive tribe, whose chief occupation is catching and curing salmon, and hunting the deer and beaver. This was reckoned an eligible situation for a fort, and here one has accordingly been erected.

There is a district called New Caledonia, generally included in the territory of Oregon, of which a short account is requisite in this place. It extends from north latitude 51° 30′ to about 56°. The principal trading post is called Alexandria, which is built on the banks of Fraser's River, in latitude 53° north. The country in its immediate vicinity presents a beautiful and picturesque appearance. The banks of the river are somewhat low; but at a little distance inland, elevations, partially diversified by groves of fir and poplar, raise their heads above the general level. This region is full of small lakes, rivers, and marshes. It extends about ten days' journey in a north and north-east direction. To the south and south east the Atnah or Chin Indian country extends about one hundred miles; on the east there is a chain of lakes, and the mountains bordering Thompson's River; whilst to the westward and north-west lie the lands of the Naskotins and Clinches. The principal rivers are Fraser's, Quesnel's, Rough Poplar, Chilcotin, and West Road. Of these, Fraser's River only is navigable. It receives the waters of Quesnel's and West Poplar Rivers, which issue from small lakes to the westward. The lakes and rivers abound in fish, such as salmon, trout, sucker, and the like. The soil is thin and poor, and the vegetation here is considerably inferior to that on the Columbia. On the banks of the chief river, and in the interior, the trees consist of poplar, cypress, alder, cedar, birch, and different species of fir, spruce, and willow. There are some wild fruits, and edible and medicinal roots, but not at all so plentifully distributed as in other parts of the territory. A number of valuable minerals are found in New Caledonia, including coal in considerable quantities. There have also been discovered rock-crystal, cobalt, talc, iron, marcasites of a gold colour, marble and limestone, quartz and granite. The animal kingdom does not differ so much from that which characterises the banks of the Columbia, as to require specific mention. Spring commences in April, when the wild flowers begin to bud, and from this period to the latter end of May the weather is delightful. In June it rains incessantly, with strong southerly and easterly winds. During the months of July and August the heat is very great; and in September the fogs are so dense that it is quite impossible to distinguish the opposite side of the river any morning before ten o'clock. October gives indications of the approach of winter; and in January the cold is sometimes most intense. In general, however, the climate may be characterised as neither unhealthy nor unpleasant. The natives prosecute the salmon fishery to a considerable extent, and their mode of catching them is very similar to that already described. Large-sized sturgeon are occasionally taken, but this fish is not relished by the natives.

Of the various Indian tribes who still inhabit the immense tract of country which we have described, our limits permit us to present only a very brief notice. Their number has been estimated at about 140,000, and they are distributed into a great many tribes, which often engage in war with each other. Many of them are excellent hunters; and the mode of fishing and preparing the article for the market shows a practised ingenuity seldom evinced by the aborigines of America. There are striking contrarieties of character between the Indian tribes; some of them being pugnacious and bloodthirsty, and others of a comparatively mild and inoffensive disposition. Their diet and their mode of living also vary considerably, but they all chiefly subsist on the fish of the rivers, and the native roots of the soil. For some years a settlement of fur traders, called Astoria, has existed in Oregon. The chief intercourse of this place is with China. The question of settling this delightful country permanently has been more than once debated in Congress; and were such settlements authorized, and rendered secure by the requisite military establishments, there can be no doubt but it would receive large accessions of emigrants. This region is claimed by the United States, on the ground of priority of discovery, examination, and occupation. It was certainly first discovered by the Spaniards, but they made no attempt either to explore or settle it. Its rediscovery belongs to Gray, an American, who entered the mouth of the Columbia in 1790–1, the river being called after the ship which he commanded. Subsequently it has been explored by navigators belonging to Great Britain, as well as to the United States. (R. R. R.)

OREL, or Orlow, a government of Russia in Europe. It is situated in north latitude between 51. 49. and 54. 59. and in east longitude between 32. 49. and 38. 57., and extends over 16,610 square miles. It is divided into twelve circles, and contains 1,270,000 inhabitants. It is rather a level district, having no mountains, and only some ranges of chalk hills, between which are valleys and some woods, that render the face of the country more pleasing to view than most other parts of Russia. The rivers and rivulets are numerous, and empty themselves, some into the Wolga, and others into the Dnieper. The chief of the streams is the Desna, which arises in the province of Smolensko; and the next is the Oka, which originates in Kursk, and runs through the whole province. The soil is the most fruitful of any of the ancient divisions of Russia, and, though not well cultivated, yields crops of all the common grains, more than is required for domestic consumption. The surplus of corn, as well as spirits distilled from it, forms a branch of the export trade; but it is exceeded by the manufactured goods, which consist of linen, iron, and steel articles, raw hides and leather, tallow and soap, glass wares, hemp, flax, linseed oil, mats, butter, hams, and wool. The only mines are those of iron; but there are quarries of alabaster, and some yielding excellent millstones. Orel, the capital of the government, as well as of the circle in which it stands, is a city situated on the banks of the river Oka, at the spot where the Orlik joins that stream, and becomes navigable for barges. It is the seat of a bishop, and is surrounded by palisades, and protected by a citadel. It is a gloomy city, built chiefly of wood, and contains 2871 houses, with about 20,000 inhabitants, depending on the trade, which, from the whole province, centres in it. It is 732 miles from St Petersburg. Long. 35. 52. 2. E. Lat. 52. 56. 40. N.

ORELLANA, Francisco, the first European, as is commonly thought, who discovered the river Amazons. In 1539, he embarked, near Quito, upon the river Coca, which farther down takes the name of Napo. From this he fell in with another large river; and, leaving himself entirely to the direction of the current, he arrived at Cape North, on the coast of Guiana, after sailing nearly eighteen hundred leagues. Orellana perished ten years afterwards, with three vessels which had been intrusted to him in Spain, without being able to discover the mouth of this river. In sailing down the river, he met with some armed women, against whom an Indian cacique had told him to be on his guard; and he thence named it "the river of the Amazons."

ORENBURG, a government of Asiatic Russia, the most westerly of the whole, having on one side Russia in Europe, and on the other the government of Tobolsk. It is bounded on the south by Independent Tartary, and is traversed by the rude tribes of the Kirghisses and Kalmucks. The aspect of the country is mountainous, as it is intersected by the most elevated part of the great Uralian chain. Many parts are fertile, as the valleys and river banks, and yield grain, not merely for the subsistence of the natives, but for exportation. Numerous flocks and herds are fed on the abundant pastures; and even the camel is bred upon the plains. The breeding of bees is pursued with activity, and is found an extremely profitable branch of industry. A great quantity of large fish and caviar taken in the Ural are exported. This province is rich in mineral wealth. Its mountains afford inexhaustible mines of copper and iron; besides which, it contains saline lakes, which are very valuable. It is divided into twelve districts, of which the principal are Orenburg proper and Oufa, the last of which contains the capital. On the Tartar frontier this province is exposed to the incursions of the Kirghisses and the Kalmuck hordes, against which a chain of forts has been erected. The population is stated at 629,426.

Orenburg, the capital of the province above described until 1702, when the government was transferred to Oufa. It is a considerable town, of an oval form, situated in one of the extended plains of Russia, and regularly fortified. It was originally built higher up the Ural range, but in 1739 was transferred 120 miles lower, and in 1742 fifty miles more. It contains nine churches and 2000 houses. It carries on an extensive trade with Tartary, Bukharia, and all the countries in the interior of Asia. One great drawback on this trade is the insecurity of travelling across the vast intervening steppes, which are inhabited by nomadic tribes, who subsist by plunder. Were this obstacle removed (and the influence of the Russian government has gone far to remove it), the trade must greatly increase. The exports consist of cloths of different qualities, particularly of a red or scarlet colour, velvets, Russia leather, linens blue and white, copper and iron utensils, sugar and other colonial produce, toys, and glass, and various species of ornaments. From Tartary these caravans bring cotton wool, India muslins and cottons, Persian silks, a little gold dust, lapis lazuli, and a few precious stones. Sheep to the number of 40,000 or 60,000, and horses to the amount of 10,000, are brought annually to the market of Orenburg. The horses are sent to Russia, and also the sheep, the tallow of which is exported from St Petersburg. A considerable trade is carried on in the sale of golden eagles, which are highly valued by the Kirghisses. Long. 52. 31. 10. E. Lat. 51. 46. N.

ORENSE, a city of Spain, in the province of Galicia. It is situated in the higher part of the country, through which the Minho flows, over which there is a magnificent bridge. It was known to the Romans by the name of Aqua Calida, on account of three fountains of warm water which rise near it. It is situated in a very fertile district, which produces great quantities of wine; but, from the bad state of the roads, the expense of conveying it to a market is more than it would sell for when it arrived there. Orense is the see of a bishop, whose spiritual jurisdiction extends over a part of the contiguous province in Portugal. It possesses four churches, two monasteries, an hospital, and a population of 30,000 souls.

ORESTES, the only son of Agamemnon and Clytemnestra, was seven years old at the period of his father's murder, when he was saved by his sister Electra, who sent him secretly to Strophius, prince of Phocis, who had married the sister of Agamemnon. Here he was educated with Pylades the son of Strophius, and afterwards proceeded to Athens. Eight years after the murder of his father he returned to Mycenæ, and, with the assistance of Pylades and Electra, put to death Ægisthus and Clytemnestra (Hom. *Od.* i. 298; iii. 303–310; Hygin. 117). For this barbarous deed he was brought to trial, but was allowed to escape on account of his father. Tyndareus, father of Clytemnestra, was his accuser (Hygin. 119), or, according to another tradition, Perilaus, son of Icarius, and cousin of Clytemnestra (Paus. viii. 33, 2). He fled to Epirus, and there founded the city Argos Oresticon; but the district of Orestias is more properly in Macedonia (Strab. vii. 326). Suffering extremely from the stings of his conscience, he consulted the oracle of Delphi how he might best expiate his crime, when he was commanded to proceed to Tauris and to bring back the statue of Artemis or Diana Tauropolos. There was a law in that country that all strangers should be sacrificed to the goddess; and when Orestes and Pylades were found by some shepherds, they were brought to Thoas, king of Tauris, who ordered them to be delivered up to the priestess of Artemis, that they might be sacrificed. Iphigenia, the sister of Orestes, had been rescued from the altar when she was on the point of being sacrificed by orders of her father, and transferred by Artemis to be priestess in her temple in Tauris. Iphigenia

Orfa. discovered on inquiry that the strangers were her own brother and his friend, and assisted them in carrying off the statue (Hygin. 120). Upon their return they are said to have passed through Cappadocia, and to have instituted the worship of Artemis or Diana at Comena and Castabela (Strab. xii. 535, 537). Another tradition made him be expiated by the Trœzenian (Paus. ii. 31, 11). On the death of Menelaus, Orestes became king of Lacedæmon; and on the failure of the royal line of Megephenthes at Argos, he annexed that city to Mycenæ. He also acquired a great part of Arcadia, and was assisted by the Phocians (ii. 18, 5). In the latter part of his life he retired to Arcadia, and probably died by the bite of a serpent (Schol. Lycoph.) at Megea, whence his bones were afterwards transferred, in the reign of Anaxandrides, to Sparta (iii. 11, 8; Herodot. i. 67). He was married to Hermione, daughter of Menelaus and Helen, by whom he had Tisamenos, who succeeded him (Hygin. 122); and by Erigone, daughter of Ægisthus and Clytemnestra, he had Penthilus (Schol. Lycoph. 1374).

ORFA, or OURFA, a pachalik or division of Asiatic Turkey. It is almost entirely formed by the windings of the Euphrates and the river Khabour, and occupies a considerable portion of the most barren part of Mesopotamia. It touches on the north and east the pachalik of Diarbekir, and the dependencies of Malatea; and on the south and west it is separated by the Euphrates from the deserts of Syria. The southern part of this province is, for the most part, flat, sandy, and uncultivated, and inhabited by tribes of wandering Arabs, who pitch their tents on the banks of the rivers and in the vicinity of the springs; but towards the north the country is mountainous and better inhabited. In the early ages of the Roman empire this division of Mesopotamia bore the name of Osrhoene, and had subsisted for 840 years as an independent kingdom, when it was reduced into the form of a Roman province by the Emperor Caracalla. It was finally swallowed up in the Turkish empire. The principal towns are Orfa, Racca, and Soverick.

ORFA, a large town, and the capital of a pachalik of the same name, in Asiatic Turkey. It is situated on the eastern side of a hill, at the commencement of a plain; so that whilst its western extremity stands on elevated ground, the eastern quarter of the town stands on a lower level; and, with some trifling inequalities, the whole town may be said to be nearly flat. It is surrounded by a stone wall, which encloses a circuit of from three to four miles, in the form of an irregular triangle; and it is bounded on the west by modern burying-grounds, gardens, hills, and vales, on the south by a rising ground, on the east and south-east by a fertile plain, terminating at the foot of a bare ridge of hills, and on the south-west is a hill nearly overlooking the town, and crowned with the walls of a ruined castle. The houses are well built, and of good masonry; they have mostly a small door of entrance from the street, with an open court, and divans in recesses below, whilst the upper story is laid out in public rooms more expensively furnished. Above is the terrace, on which are placed sofas and beds, where, in hot weather, the family sleeps. The streets are narrow, but having a paved causeway on each side, with a central channel for water, and being more or less sloping downwards, are generally clean. The bazaars are numerous and well supplied, and are appropriated to the manufacture and sale of particular commodities. Most of these are commodious; they are also covered, and are always fresh and cool, being sheltered both from the sun and rains. The bazaar in which muslins, cottons, and other piece goods are exposed, is from twenty to twenty-five feet in width, and from thirty to forty feet in height, covered in by a range of fine domes in succession, admitting light and air by a sort of lantern windows in the roof. The khans and caravanserais are numerous, and some few are excellent. The Khan Khoolah-Oghlee, on the outskirts of the town, is spacious, and capable of accommodating in its central court 100 camels with their lading, in the adjoining stables as many horses, mules, and asses, and in the chambers above there is room for 200 persons. The Khan-el-Goomrook, or the custom-house khan, consists of an open court 100 feet square, and paved throughout. Through this court runs a fine broad stream of transparent water, crossing it diagonally, and serving for the watering of horses, the ablutions of the pious, and the washing and cleaning of manufactures. There are, above and below, about 100 chambers large enough to accommodate eight or ten persons each. There are fifteen mosques crowned with minarets. The most magnificent of these, though not the largest, is that of Ibrahim el Khaleel, or the mosque of the patriarch. It is situated on a lake filled from a clear spring which runs in the south-west quarter of the town, and abounds with fine carp, in which the superstitious people believe that, owing to the care of the patriarch, no impression can be made by any process of cooking. The grand façade of this mosque is a square pile of building, over which rise three large domes of equal size; and a lofty minaret springs up from amidst a cluster of tall cypress trees. At each end of this central pile, towards the stream, are flights of steps descending to the water's edge, for the ablutions of the pious. The wings are terminated by two solid masses of building, uniform in design, and "completing," says Buckingham, "one of the most regular edifices of this kind to be found perhaps in Turkey." The largest of the mosques at Orfa has a square steeple, and this form is also repeated in one of the smaller ones. The castle is on the south side of the city; the ascent is very steep, and is about half a mile in circumference, surrounded by a deep ditch cut in the rock, which can be filled with water from the river Scirtus. On this rock are the ruins of a building called by the Arabs the palace of Nimrod, consisting of two lofty and fine Corinthian pillars, and of some subterranean apartments, apparently of great antiquity. There are four or five large baths, some reported to be good; but the one which was seen by Mr Buckingham was, though spacious, dirty and badly attended. The manufactures of the town are chiefly confined to articles of the first necessity, namely, to coarse woollen cloths, used for shirts and drawers, and, when printed, made into gowns for females, shawls for the head, and some other articles. The process used for printing cottons is tedious. A few carpets are made, of a very good quality, also silk bands and tapes, hair-cloth for sacks and bags, and every description of saddlery and smith's work, as well as of mason's work and carpentry. Cook-shops and coffee-houses abound everywhere; and, during all the summer, there is an abundant supply of solid ice brought down from the summits of Mount Taurus, and sold at present for a farthing a pound. It is the seat of a considerable inland trade, being a thoroughfare for caravans passing from Aleppo into the interior of Persia. The population may be estimated at 50,000, amongst whom are 2000 Christians and 500 Jews, the rest being all Mahommedans. The Christians are chiefly Armenians and Syrians, each of whom have a separate church, and live in a separate quarter.

Orfa is of great antiquity, and is considered by all the learned Jews and Mahommedans, and by Christian scholars, as the Ur of the Chaldees. It was the Edessa of the Greeks and Romans, and was frequently taken and retaken during the wars between the Persians and Romans. In the reign of Heraclius, about A. D. 637, Orfa was taken by the Saracens, and its walls levelled with the dust. It was retaken by Baldwin in 1097, who founded the first principality of the Franks or Latins. It was also taken by Genghis Khan about the year 1144, and thirty years afterwards by

Saladdin. It was sacked by the Moguls in the thirteenth century; and two centuries afterwards suffered the same calamity from the armies of Tamerlane. It was visited in 1544 by Tavernier, in 1738 by Pococke, who describes it as being in a flourishing state, and in 1766 by Niebuhr, who gives the same account of it. It is sixty-seven miles from Bir, and 232 from Diarbekir. Long. 38. 25. E. Lat. 36. 50. N.

ORFFYREUS'S WHEEL is a machine so called from its inventor, who asserted it to be a perpetual motion. This machine, according to the account given of it by s'Gravesande, in his *Œuvres Philosophiques*, consisted externally of a large circular wheel, or rather drum, twelve feet in diameter, and fourteen inches deep, being very light, as it was formed of an assemblage of deals, having the intervals between them covered with waxed cloth, to conceal the interior parts of it. The two extremities of an iron axis, on which it turned, rested on two supports. On giving a slight impulse to the wheel in either direction, its motion was gradually accelerated; so that after two or three revolutions it acquired so great a velocity as to make twenty-five or twenty-six turns in a minute. This rapid motion it actually preserved during the space of two months, in a chamber of the landgrave of Hesse, the door of which was kept locked, and sealed with the landgrave's own seal. At the end of that time, however, it was stopped, to prevent the wear of the materials. The professor, who had been an eye-witness of these circumstances, examined all the external parts of it, and was convinced that there could not be any communication between it and any neighbouring room. Orffyreus, however, was so incensed, or pretended to be so, that he broke the machine in pieces, and wrote upon the wall that it was the impertinent curiosity of Professor s'Gravesande which made him take this step.

ORFORD, a borough and market town of the county of Suffolk, and hundred of Plomsgate. It is a part of the parish of Sudborne, though separated from it, and stands at the confluence of the river Ore and Alde, ninety miles from London. Orford was a place of some trade till its harbour became chocked up. It has a mayor, recorder, twelve burgesses, and eight portmen, and returned two members to the House of Commons till 1832, when it was disfranchised. It is remarkable for the ruins of an ancient tower, which serves as a land-mark to vessels. It gives the title of baron to Earl Walpole. The population amounted in 1801 to 751, in 1811 to 737, in 1821 to 1119, and in 1831 to 1302.

ORGAL, amongst dyers, denotes the lees of wine dried.

ORGAN, in general, is an instrument or machine designed for the production of some certain action or operation; in which sense the mechanical powers, machines, and even the veins, arteries, nerves, muscles, and bones of the human body, may be called *organs*.

Organ.

ORGAN, by far the most noble and imposing of all musical instruments. It is quite inconsistent with the design and limits of this work for us to enter into all the details of the nature and structure of the organ. They would fill a volume, and require many illustrative plates. We shall, however, endeavour to give such a general idea of the nature of the instrument as may satisfy those readers who are not professionally interested in the subject; and we assure them that their own inspection of the mechanism of an organ (which is easily attained in every large town) will afford them more clear and satisfactory knowledge than hundreds of pages written in explanation of its construction. For minute details, we refer to *L'Art du Facteur d'Orgues*, by F. Bedos de Celles, published at Paris in 1766 and 1778, in folio, with 137 plates. This is considered, even now, as the best and most complete work on organ-building. It is a pity we have none such in the English language. See also the Abbé Vogler's German works upon organ-building, and G. Serassi's *Lettere sugli Organi*, printed at Bergamo in 1816; together with Reports of the French Institute upon M. Grenié's improvements on the organ. We suspect that the general want of improvement in organ-building in Great Britain may be traced to the absence of such works, and some others, in our own language, for the instruction of our organ-builders. This may also explain, in some degree, why almost all the best organs in England were constructed by foreigners. Recently, however, we are happy to perceive a spirit of emulation arising amongst our native organ-builders; and we have little doubt that the ingenuity and superior workmanship of British artisans will soon enable us to vie with, or excel, the best organ-builders of the Continent. But, to do this, we must cast aside all national prejudices as to organs, &c. and meet foreigners upon a fair and liberal ground of competition.

The earlier history of the organ is extremely obscure. A small and imperfect instrument, somewhat on the principle of the organ, may have been known to the ancients; but surely nothing like our great church-organ. We read of ancient *hydraulic* and *pneumatic* organs; but such distinction is so far erroneous, inasmuch as organ-pipes could not be made to sound by having *water* forced through them. The water must have been a moving power only, to impel the *wind* into the pipes. It would seem that the Greek and Latin terms ὄργανον and *organum*, translated by the English word *organ*, originally signified an instrument or machine of any kind, and were afterwards applied to musical instruments of all kinds. "*Organa dicuntur omnia instrumenta musicorum*," says St Augustin. Still later, according to St Isidore, these names, ὄργανον and *organum*, were applied to none but wind-instruments. In modern times the term organ, in a musical sense, came to signify only the instrument which we now know under that name. The passage in Eginhard's Annals which has been interpreted the sending of *an organ* by Constantine Copronymus to King Pepin in the year 757, may more probably mean "*various musical instruments*," since the words are, "*Constantinus Imperator Pipini regi multa misit munera, interque et organa*," &c. A writer of the sixteenth century has ventured to describe the supposed *organ* sent to King Pepin; and, by force of imagination, makes it out to have been a grand organ with pedals. In Luitprand's History (book vi. c. 2) there is a curious passage regarding an instrument sent to the Emperor Constantine in 950:—"Erat Regia ornata sumtuosissime, ibi ænea inaurata arbor ante ipsius imperatoris solium effulgebat, expansis magnum in modum ramis aereis atque inauratis; in his frequentissimæ variarum specierum aves arte confictæ, quarum singulæ speciei proprias voces cantusque emittebant, incredibili arte." In the second volume of Gerbert (*De Cantu et Musica Sacra*, plate xxviii.) will be found a representation of a tree of this kind with birds upon it. The Chronicle of Albericus adds to the singing of the birds before Constantine, "the roaring of enormous gilded artificial lions." (See Gerbert, vol. ii. p. 151.) That such birds can be made, is certain from Maillardet's beautiful little artificial bird, which started up out of a gold snuff-box, fluttered its wings, and sang with a pipe so clear and loud as to fill a large room. It would appear that, in the rude instruments called organs in the eleventh and twelfth centuries, the pipes were disposed in such a manner that every sound in its finger-key compass caused the fifth and the octave of that sound to be heard above it. Such a succession of fifths and octaves was called "organum," no doubt *par excellence*. From this and the old and extraordinary specimens of *Biscantus*, or *Discantus*, given by Gerbert and others, and alluded to in our article MUSIC (page 623), we are inclined to believe that the modern mixture-stops of the organ have originated. We leave the consideration of the ancient organs to antiquaries, and now proceed to the modern organ, which seems to have assumed something of its present form in the fifteenth century.

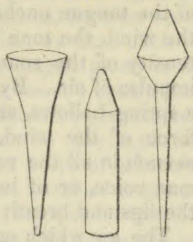
The mechanism of the modern organ has been much improved at different times by different builders. The family of the Antegnati, of Brescia, were amongst the earliest famous organ-builders in Italy in the fifteenth and sixteenth centuries. In the eighteenth century there were in Italy many celebrated organ-builders, amongst whom Serassi of Bergamo, and Callido of Venice, each constructed upwards of three hundred organs.

Most of our readers probably know already that the great organ is a complex wind-instrument, consisting of a great number of pipes of different sizes, formed of wood and of different kinds of metal, some of which are flute-pipes or mouth-pipes, and others reed-pipes; whilst all of these are made to sound by means of compressed air applied to them through certain channels, by bellows worked either by human force or by mechanism. There are different kinds of organs, from the Lilliputian bird-organ up to the great church-organ. We pass over the minor ones, including the chamber-organs and the smaller chapel-organs, and proceed to the great church-organ. We need not describe its front, nor the case in which its mechanism is contained. The great church-organ has usually three rows of finger-keys, placed above each other like steps. In some of the largest organs there are four, or even five such rows of keys. Besides these, there are rows of pedals, or foot-keys, which act upon the larger pipes of the organ. The bellows communicate, by a wind-trunk, with wind-chests, or reservoirs of air, whence the wind is distributed to the various pipes of the organ when the finger-keys or the foot-keys (pedals) are pressed down. Attached to the upper part of each wind-chest is a sound-board, as it is rather improperly called. This sound-board consists of two parts, an upper and an under board, the latter of which is much thicker than the other. Both of these are formed of planks of wood laid horizontally side by side, and accurately joined together at their edges. In the under side of the lower board several rectangular grooves or channels are cut parallel to each other, and carried along nearly the whole length of the board, and as far as there are stops in the organ. In these channels are fixed bars of wood, so as to render each channel or *partition* completely separate from every other. In the upper side of this board are cut a number of other rectangular channels or grooves running across the board, and at right angles with the under grooves. Into these upper grooves are exactly fitted wooden sliders, or registers, which run the whole length of the grooves. These sliders can be drawn out so far or pushed in at pleasure, by a mechanism attached to the draw-stops that are placed on the right and left in front of the organ. Holes corresponding with the number or rows of organ-pipes placed above the sound-board, are pierced through the latter into the above-mentioned channels, and also through the sliders or registers, in such a manner that when the latter are drawn out, their holes correspond with those of the sound-board, and allow the air from the wind-chest to pass through them and through the other holes in the sound-board; whilst, on the contrary, when the sliders are pushed in, they completely prevent any air from passing from the wind-chest to the pipes above the sound-board. Above all, and corresponding with the upper holes of the sound-board, are placed the pipes, fitted in by their conical feet to what are called the stock-boards. There are rows of thin boards, called racks, which are sustained by pillars of wood, and which receive the upper part of the feet of the pipes in holes made for the purpose. Opening into the wind-chest, and fixed upon the under side of the sound-board, are spring-valves, which are connected, by a particular mechanism, with the finger-keys and pedals; and which, when the sliders are drawn out, and the keys and pedals pressed down, are made to open, and so to admit the air from the wind-chest into the channels or partitions belonging to the different rows of pipes constituting the various stops of the organ. The pedals and the finger-keys communicate with these spring-valves by means of an apparatus of trackers, cranks, and rollers, acting upon pull-down wires that pass through the bottom of the wind-chest, and are attached to these valves. The draw-stop movement, by which the sliders are drawn out or pushed in, consists of a similar mechanism. In some organs these sliders are superseded by another contrivance. Thus, in what are called by the Italians *somieri a vento*, the opening of a given stop or register is not effected by drawing out a wooden slider, so as to make its apertures correspond with those in the sound-board; but by pulling open, all at once, in the channels of the sound-board, as many small valves as there are pipes to that given stop. These small valves are made to open by pulling out a draw-stop, and to shut by pushing it in again. They are considered to have many advantages over the ordinary slider, as being more durable, and less subject to the influence of changes of the weather.

A stop is called simple if it consists of one row of pipes, and compound if it consists of more than one row. As to the different rows of finger-keys, each communicates with what is really a separate organ, or collection of pipes, with its peculiar wind-trunk, wind-chest, sound-board, &c. These different organs are generally three, and are called the great organ, the choir-organ, and the swell-organ. The middle row of keys is connected with the great organ, the lower with the choir-organ, and the upper with the swell-organ. The swell-organ has its pipes enclosed in a wooden box furnished with a sliding door, or a hinged door, which is gradually opened or shut by mechanism moved by the performer's foot applied to a pedal. All these different organs, constituting the great church-organ, are supplied with air by the same bellows, and by suitable wind-trunks connected with the bellows. The bellows now generally used are horizontal ones, instead of the old ones resembling blacksmiths' bellows. For some improvements in the sound-board and its appurtenances, see Serassi's *Lettere sugli Organi*.

We have already mentioned, that the pipes of an organ generally consist of mouth-pipes and of reed-pipes. With regard to the mouth-pipes, their nature may be pretty well understood by any one acquainted with the upper part of the common English flute, or the flageolet. The reed-pipes are explained in a subsequent part of this article. What we have said regarding sonorous tubes in the article Music, pages 608, 613, 615, may assist the reader in understanding our notices of organ-pipes. Organ-pipes are either open, or stopped, or half-stopped. The stopped ones have a plug or tompion inserted into their upper end, and pushed down or pulled up to regulate the pitch. The half-stopped ones have a kind of chimney at the top. Some of the middle-sized ones are partly stopped, and have also on each side of the mouth a kind of ear of metal, by bending of which outwards or inwards, the pitch of the pipe may be regulated. The largest pipes are square ones of wood, and belong to the pedals. In some great organs, the largest open pipe is thirty-two feet in length. The other pipes are made of wood or of metal. It has been observed by organ-builders and others, that the quality of tone (*timbre*) of pipes depends much upon their proportions in length and width, the material of which they are made, &c.; and also upon the form of their open top, by which the wind escapes. We shall have occasion to notice this again, when describing some of Grenié's improvements. A reed-pipe, with a conical tube which has a bell-shaped end, as in fig. 1, gives the most brilliant sound. If the pipe have a reversed conical top, as in fig. 2, the sound becomes dull. If two similar truncated cones placed base to base be fixed to the wider end of a long conical tube, as in fig. 3, a reed-pipe so formed will give fulness and strength to the sound. Theory affords no satisfactory explanation of these facts. The *timbre* of the stopped and of the half-stopped pipes is softer and duller than that of the open ones. Pipes of pure tin have long been known to possess a *timbre* more clear and penetrating than those made of tin mixed with lead. Some years ago, a Bohemian organ-builder made some of his pipes of zinc, which was said to answer better than even tin. No doubt various simple and compound metals, and various other substances that have not yet been used in the making of organ-pipes, might be employed with advantage to produce a still greater variety of *timbres* and effects; and for the same purpose, various modifications of the ordinary forms of pipes might also be employed.

Fig. 1. Fig. 2. Fig. 3.

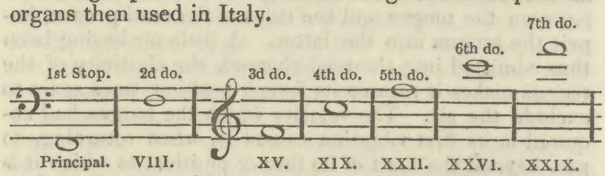


The pipes and stops of an organ differ in number and kind according to the size of the organ, the fancy of the builder, and the taste of the public. In some Dutch, German, and Italian organs, there seems to be a superfluity of stops. An immense organ at Weingarten, in Germany, is described as having sixty-six stops and 6666 pipes. The great organ at Haarlem contains sixty stops, and its largest pipe is thirty-two feet in length. For an enumeration of the stops of three of Silbermann's organs at Dresden, we refer to a Ramble among the Musicians of Germany, published at London in 1828 (pp. 193, 194, 195). One of the largest organs in Italy is said to be that built in 1733, by Azzolino della Ciaja, for the church of the Cavalieri di S. Stefano at Pisa. It is said to have four rows of finger-keys, and more than 100 stops. Another remarkable one is in the church of S. Alessandro in Colonna, at Bergamo. It was built by Serassi in 1782, and has three rows of finger-keys, and about 100 stops. In it the first and second rows of keys serve for the great organ, and the second organ or choir-organ, built together in the same part of the church. The third row of keys is connected with mechanism, which passes under ground and extends to a distance of about 115 feet English, with a third great organ placed in another part of the church, and directly opposite to the first. Notwithstanding such a distance from the keys, the third organ obeys them as readily as the first one does. Its lowest pedal-pipes consist not only of mouth-pipes, but also of reed-pipes. The following is a brief description of another organ built by Serassi in 1796. "Two rows of finger-keys, the upper for the great organ, the *ripieno* of which consists of the following stops: Two principal soprani; two principal basses; octave, twelfth, fifteenth, twenty-second, twenty-sixth, twenty-ninth, two thirty-thirds, two thirty-sixths, and twelve deep bass stops belonging to the chromatic scale, with the octaves of these, all, however, governed by one register. The different stops belonging to the great organ are, the sesquialtera; two cornets; flute in octave; flute in twelfth; German-flute; vox humana; viola; bassoon; English horn; trumpets; trombones; cymbals; kettle-drums, and bass-drum, the last being managed by a pedal. The lower row of manuals or finger-keys serves for the second organ, or choir-organ. It has its *ripieno*, composed of principal, octave, fifteenth, nineteenth, twenty-second, twenty-sixth, and twenty-ninth; and has, besides, the stops of cornet, flute in octave, vox humana, and violoncello. By means of a pedal moved by the right foot, all the stops of the first organ can be opened or shut at once."

Of the different stops or registers of an organ, some derive their names from the instrument the tone of which they imitate, and some from the relation in pitch which they bear to the sounds of the diapason stop, as octave, twelfth, fifteenth, seventeenth, and so on. We subjoin a brief account of the most usual organ-stops. I. *Open diapason;* consists of metal mouth-pipes open at the upper end, and extends through the whole scale of the organ, as its name diapason imports. II. *Stopped diapason;* mouth-pipes generally of wood, and their pitch an octave below that of the open diapason. They are stopped at the upper end. III. *Double diapason;* wooden mouth-pipes, open at the upper end, and their pitch an octave lower than those of the open diapason. They are generally confined to the two lowest octaves of the organ's compass. In some of the largest organs, the gravest sound of these is rendered by an open pipe thirty-two feet in length. IV. *Principal;* metal mouth-pipes, the pitch of which is an octave above the open diapason. The *principal* is the first stop tuned; and then, from it, all the other stops. V. *Dulciana;* a metal mouth-pipe stop, tuned in unison with the open diapason. The sweetness of its tone originates in the length and narrowness of its pipes. VI. *Twelfth;* metal mouth-pipes tuned a twelfth above the open diapason. VII. *Fifteenth;* metal mouth-pipes tuned an octave above the principal. There are, in some organs, stops named *tierce* or *seventeenth, larigot* or *nineteenth, twenty-second, twenty-sixth, twenty-ninth, thirty-third,* &c., tuned respectively at these intervals above the open diapason. VIII. *Flute;* metal and wood mouth-pipes, in unison with the *principal.* IX. *Trumpet;* reed-pipes of metal, in unison with the open diapason. X. *Clarion* or octave trumpet-stop; metal reed-pipes tuned an octave higher than those of the trumpet stop. XI. *Bassoon;* reed-pipes, in unison, as far as their compass reaches, with pipes of the open diapason. XII. *Cremona,* or properly *krum-horn;* reed-pipes, in unison with the open diapason. XIII. *Oboe;* reed-pipes, in unison with the open diapason. XIV. *Vox humana;* reed-pipes, in unison with the open diapason, and intended to imitate the human voice, a function which in general they perform very unpleasingly.

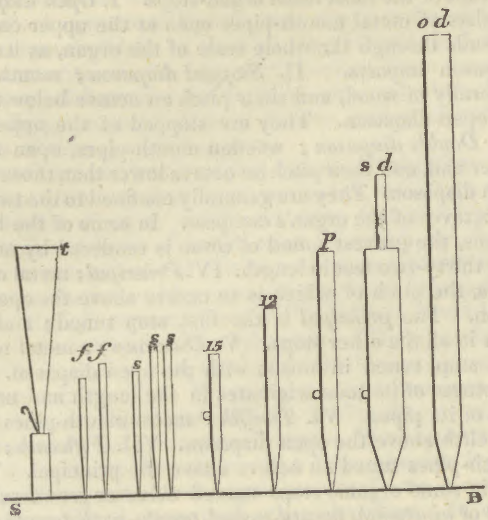
Amongst the *compound* stops used in organs are, I. The *sesquialtera,* consisting of four or five rows of open mouth-pipes at the intervals of seventeenth, nineteenth, twenty-second, twenty-fourth, or twenty-sixth, above the open diapason. II. The *cornet,* a stopped diapason, principal, twelfth, fifteenth, and seventeenth. III. *Mixture* or *furniture* stop, consists of several ranks of pipes nearly the same as those of the sesquialtera, but some of them of a higher pitch. Vogler denounces the *mixture-stops* as "*insignificant.*" We have sometimes heard a harsher term applied to them.

In Costanzo Antegnati's *Arte Organica* we find the following exposition of the series of registers or stops of the organs then used in Italy.



In order to enable the reader to form a clearer idea of the distribution of the pipes of an organ, we subjoin a sketch of a row of the usual pipes of the great organ (as contradistinguished from the choir and swell organs), and as these pipes stand upon and are inserted in the top of the sound-board. To simplify the diagram, the rack-board and pillars are not represented here. The letter *t* indicates the trumpet; *ff,* furniture; *sss,* sesquialter; 15, fifteenth; 12, twelfth; *p,* principal; *sd,* stopped diapason; *od,* open diapason; SB, the top of the sound-board. The other rows of pipes are, of course, to be imagined as placed behind those pipes here represented, and as extending, in their respective ranks, the whole length of each stop or register, in lines at right angles with the line formed by the row of pipes shown in the diagram.

Fig. 4.



Not many years ago, M. Grenié, a French amateur of music, introduced several important improvements in the construction of reeds for organ-pipes. (See the Reports of the French Institute, &c.) His reed (AB in the annexed figure 5) was made of wood or copper, square-edged, and of the form of a parallelopipedon. [In order to show the difference between the construction of M. Grenié's reed and the common organ-pipe reed, we add a diagram of the latter, fig. 6.] The tongue was a thin plate of brass, of an even surface, and cut in a rectangular shape, so as to fit almost exactly the grooved face of the reed. A strong wire-spring *cc* kept down this tongue firmly upon the reed, at the proper length, so as to regulate the tongue's vibrations. The result of such a construction is, that when this reed, enclosed in its tube, is made to sound by air forced into the porte-vent DEF, by the aperture at F, the air thus introduced not obtaining admittance into the reed between the tongue and the sides of the reed-groove, impels the tongue into the latter. A little air having been thus admitted into the reed-channel, the elasticity of the tongue makes it resume its former position, so as again to exclude the air. The velocity which the tongue had acquired in its first vibration causes it, when returning, to pass beyond the limit of its former position, to which it is again brought back by the resistance of the air, and by its own elasticity, and whence the impulse of the current of air from the porte-vent again forces it into the reed-channel. The advantages of this construction are, that the tongue does not strike against the edges of the reed, as in the common reed-pipes, which thereby produce a harsh and uneven tone; and that its movements are smooth and regular, since it has nothing to encounter in its vibrations but the air itself. The sound of M. Grenié's reed-pipes is said to be, in the most acute as well as in the gravest of them, as sweet and pure as that of flute-pipes. M. Grenié adapted the degree of strength and rigidity of each tongue to the breadth of the reed-channel which it

Fig. 5.

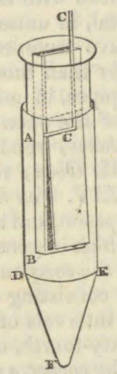


Fig. 6.

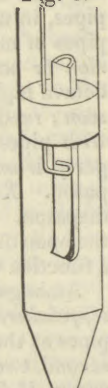
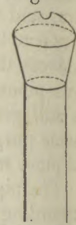


had to cover, so that the stream of air could never throw it into vibrations around its axis. The strength of the spring-wire also kept the length of the vibrating portion of the tongue unchanged; so that, whatever the force of the wind, the tone never altered its pitch. Only the intensity of the sound was affected by the greater or less impulse of air. By means of a pedal, the performer moved a spring-bellows, and, by thus regulating at pleasure the force of the wind, could obtain a *crescendo* and *diminuendo* in all the reed-pipes, as perfect as that of the human voice, or of instruments modified in their sounds by the lips and breath of the performer.

The air which causes these reeds to vibrate passes out through open pipes, bevelled off into a cone, and terminating in a hemisphere, fig. 7. This form is said to give roundness and strength to the tone.

Fig. 7.



M. Grenié, when constructing his reed-pipes, was for a long time checked by a very curious phenomenon. He was at first occupied with the gravest octave of which the sound C is in unison with an open flute-pipe of eight feet; and had constructed a certain number of pipes, in giving wind to all his reeds by pipes of the same length, fig. 8. But when he had reached the first notes of the tenor compass, still continuing to construct his porte-vents in the same manner, the reed would not sound at all. He in vain increased and diminished the wind, in vain lengthened and shortened the tongue; the reed remained mute, or produced only very bad sounds. At last, after many attempts, M. Grenié thought that the length of the pipe which conducts the wind to the reed might have some unknown influence upon its vibration. He therefore substituted for his fixed tubes two pipes, of which the one was made to slide within the other, so that he could gradually vary the whole length. He tried this change of length until the reed produced a clear, pure, and sustained sound. He found also, that in order to obtain the tenor sounds in all their fulness, it was necessary to make the porte-vent much longer than for the sound immediately preceding, and this length always went on diminishing for the most acute octaves, as is represented by fig. 9. Then the tops

Fig. 8.

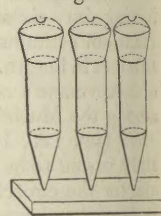


Fig. 9.

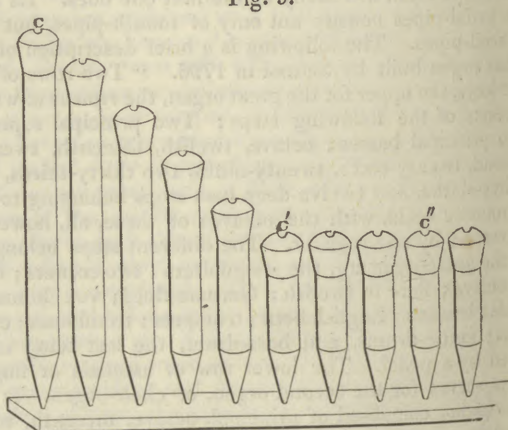

of the pipes formed the curve C C′ C″. This seemed to indicate that, by prolonging that curve, one would obtain the most favourable dimensions for those pipes of the first octave which M. Grenié had at first made of equal lengths. But, to his great surprise, he found that there was no advantage whatever in doing so; but that, on the contrary, the sounds became very dull and irregular. He therefore reasonably adhered to his first construction, which, nevertheless, he still purposed to improve, by afterwards making all his porte-vents sliding tubes, so that each of them might have the most favourable length given to it. He has since constructed, on this same model, open reed-pipes of sixteen feet, which sound with very remarkable distinctness, strength, and regularity. In this case the tongue is a flat slip of copper, in length 0·240 of a metre, in breadth 0·035 of a metre, in thickness 0·003 of a metre; equal respectively to 9·449040, and 1·377985, and 0·118113 English inches and decimal parts. Its vibrations are so powerful, that they cause the pipe in which it is placed, the porte-vent over which it is mounted, and all neighbouring elastic bodies, to tremble. Of course, in order to make it sound, a powerful and well-managed bellows-force is necessary. That which M. Grenié employed was perfect in regularity and power. It had a double current of air, and was worked by one handle. M. Grenié obtained a patent for his improvements. He considered the mixture-stops in common organs as productive of nothing but bad effects, and therefore excluded them from his organ. (See report by Cherubini, Catel, Baillot, &c. in 1811.) We have given so full an account of Grenié's improvements, in order to excite the attention of British organ-builders to this subject, and induce them to discover many more improvements of which our organs are unquestionably susceptible.

One of the greatest steps to improvement in English organ-building was made upwards of twenty years ago, by Messrs Flight and Robson of London, in the construction of their magnificent organ, called the Apollonicon. It was exhibited to the public, and attracted vast numbers of visitors. The ingenuity of its mechanism, the excellence of its workmanship, the fineness of its tone, and the novelty and grandeur of its effects, were universally acknowledged. This fine instrument was played either by means of the revolutions of three large cylinders, or else by means of six different sets of finger-keys acted upon simultaneously by six different performers. The Apollonicon was about twenty-four feet high and twenty broad. We heard it in 1817, and were much struck by its varied and powerful effects. However, the room in which it was placed was neither sufficiently large, nor so proportioned in form, as to display the powers of this organ to the best advantage. This fine instrument alone is sufficient to bear us out in what we have said at the beginning of this article, as to the certainty of English organ-builders being able to rival, or to excel, the foreign ones, if they choose to exert themselves.

Several methods have been proposed in England to render the intonation of the organ less imperfect, by dividing the octave into a greater number of intervals than the usual twelve: amongst others, that employed in Hawke's patent organ, described in the thirty-sixth and thirty-ninth volumes of the Philosophical Magazine. Hawke divided the octave into seventeen intervals. Loeschman's patent organ was another of this kind. He divided the octave into twenty-four intervals, which were produced by six pedals and twelve finger-keys. (See description in vols. xxxvii. xxxviii. of Philosophical Magazine.) In 1810, the Rev. Henry Liston, a clever and ingenious Scottish clergyman, obtained a patent for an instrument, constructed by Messrs Flight and Robson, which he named the *Euharmonic Organ.* (See vol. xxxvii. of Philosophical Magazine.) Another organ, similar to the one last mentioned, was made for Mr Liston by the same builders. (See Philosophical Magazine, vol. xxxix.) It had eleven pedals, six of which were the same as those in Loeschman's organ. In the second organ built for Mr Liston, there was a contrivance for an occasional alteration of the pitch of the pipes, in the requisite degree, by means of flat metallic plates, which, when acted upon by the pedals, were brought, at due distances, over the tops of the open pipes, or opposite to the mouths of the stopped pipes, so as to flatten the pitch when this change was required.

The object of Mr Liston's organ was to supersede temperament; but although its ingenuity and its effects were admired by many of the best musicians in London, the complexity of its manuals and pedals prevented it from ever being generally adopted. And this has been the fate of all such instruments, in modern as well as in ancient times; for attempts of a similar kind were made, centuries ago, to introduce such minute subdivisions of the octave into keyed instruments. The Spanish writer Salinas, in his work *De Musica* (lib. iii. c. 27), speaks disparagingly of an instrument called an Archicymbalum, which had been constructed in Italy above forty years before the publication of his work in 1577, and in which every tone was divided into five parts. "Non silentio prætermittendum arbitror instrumentum quoddam, quod in Italia, citra quadraginta annos fabricari cœptum est, ab ejus autore, quisquis ille fuit, Archicymbalum appellatum. In quo reperiuntur omnes toni in quinque partes divisi: ex quibus tres vindicat sibi semitonium majus, et duas semitonium minus, a quibusdam magni nominis musicis in pretio habitum, et usu receptum: eo quod omnis in eo sonus habet omnia intervalla, atque omnes consonantias (ut sibi videntur) inferne, et superne, et post certam periodum ad eundem, aut equivalentem sibi sonum post 31 intervalla reditur," &c. In the latter part of the last century, F. X. Richter, chapel-master in the cathedral of Strasburg, usually composed upon a clavichord, which had twenty-one sounds to the octave, and which then seemed to be upwards of two hundred years old. Richter died in 1789, aged eighty.

For some hints regarding the proper use of the organ, see the article Music (vol. xv. p. 644). Those who wish to extend their knowledge of this subject will find abundance of information upon the history and the construction of the organ, and the art of playing it, in works published in Germany, France, and Italy. The German works are the most numerous. (G. F. G.)

ORGANIST, a person who plays upon the organ. In Germany and Prussia, the requisites of a good organist are so many in point of musical education, and musical taste, and mechanical skill, that hardly any of the organists of other countries would venture to enter into competition with the German or Prussian organists. All the best works upon the art of organ-playing are in the German language. We may cite, as one of these, Rink's work upon organ-playing.

ORGANO-LYRICON, a musical instrument invented at Paris in 1810, by M. de Saint Pern. Its height is about eight feet two inches English, its breadth six feet six and a half inches, its depth about four feet four inches. It consists of a piano-forte, coupled with twelve different wind-instruments, viz. three kinds of flutes, an oboe, a clarinet, a bassoon, horns, trumpet, and fife. It has two rows of finger-keys. The lower row belongs to the piano-forte; but, by an ingenious mechanism, and according to the depression of the keys by the performer, it may be made to sound either the piano-forte alone, or a flute, or an oboe, or to unite them all. The upper row of finger-keys has no action on the piano-forte; but, by management of the pressure, it causes the German flute or the oboe to sound, and produces *rinforzi* by the gradual re-union of several wind-instruments. Independently of these functions, this row of finger-keys is destined for a great church-organ placed above it. The correspondence between the two rows of finger-keys is such, that they may, at the will of the performer, act together or separately, or even partially. The finger-keys are singularly light in their touch, even at their maximum of depression. At the bottom of the instrument there are pedals for the double bass, and for other combinations. The wind-chests are numerous, and of such capacity that the wind of the large bellows which fill them cannot produce in them any augmentation injurious to the purity of the *timbre* and the trueness of the intonation. In this instrument, by means of ingenious contrivances, the inconveniences of an irregular supply of wind have been carefully avoided. A double pedal for the right foot enables the performer to work the bellows himself when he is alone. An adjacent pedal, turned the opposite way, enables an assistant to do this. But, to avoid the trouble of these pedals, M. de Saint Pern placed in an adjoining room a large piece of clock-work, moved by a weight of fifty pounds, which served instead of a bellows-blower. The performer has beside him a mechanism that communicates with the clock-work, and, by means of a click and spring, leaves the weight going, or stops it at pleasure. See Report read to the French Institute on the 10th of September 1810; also Report of the French Conservatory of Music, 12th of August 1810, where it is said that "M. de Saint Pern's organo-lyricon might, in a large room or a chapel, hold the place of an orchestra, and imitate nearly all the effects of one."

ORGIA, feasts and sacrifices in honour of Bacchus, which were held every third year, and chiefly celebrated by wild, distracted women, called *Bacchæ*. The chief solemnities were performed in the night, to conceal, perhaps, their shocking impurities; and a mountain was generally chosen as the place of celebration. They were instituted by Orpheus, and from him are sometimes called *Orphica*. Authors are not agreed as to the derivation of the word; but if we consider the frantic proceedings of the Bacchanalians, ὀργη, *furor*, bids fair for being the true etymology.

Orgia, according to Servius, was a common name for all kinds of sacrifices amongst the Greeks, as *ceremoniæ* was amongst the Romans.

ORGUES, in the military art, are thick long pieces of wood, pointed at one end, and shod with iron, which being kept clear one of another, hang each by a particular rope or cord, perpendicularly, over the gateway of a strong place, to be let fall in case of the approach of an enemy.

Orgues is also used for a machine composed of several harquebuss or musket barrels bound together, by means of which several explosions are made at the same time. It is used to defend breaches and other places attacked.

ORGYA, ὀργυια, an ancient Grecian measure containing about six English feet.

ORIBASUS, a celebrated physician, greatly esteemed by the Emperor Julian, in whose reign he flourished. At the request of the emperor, he abridged the works of Galen, and of all the most respectable writers on physic; and he accompanied Julian into the East, but his skill proved ineffectual in the attempt to cure the fatal wound which his benefactor had received. After Julian's death he fell into the hands of the barbarians.

ORICHALCUM, or Aurichalcum, a metallic substance resembling gold in colour, but very inferior in value. It was well known to the Romans, who often took advantage of its resemblance to gold; for some sacrilegious characters, who could not resist the temptation of taking gold from temples and other public places, chose to conceal their guilt by replacing it with orichalcum. It was thus that Julius Cæsar acted when he robbed the capitol of three thousand pounds weight of gold; in which he was followed by Vitellius, who despoiled the temples of their gifts and ornaments, and replaced them with this inferior metal. It has been a matter of dispute with philosophers and others, what the composition of this metal could be, or how it was procured; it is probable, at least, that it was analogous to our brass, if not wholly the same with it.

The Romans were not only in possession of a metallic substance, called by them *orichalcum*, and resembling gold in colour, but they knew also the manner of making it; and the materials from which they made it were the very same with those from which we make brass. There are, indeed, authors of great repute who think very differently, and consider the art of making brass as an invention wholly modern. Thus M. Cronstedt does not think it just to conclude from old coins and other antiquities, that the making of brass was known in the most ancient times; and the authors of the French *Encyclopédie* assure us that our brass is a very recent invention. It appears, however, from Pliny (*Nat. Hist.* lib. xxxiv. § 2), and from the concurring testimony of other writers, that *orichalcum* was not a pure or original metal; but that its basis was copper, which the Romans changed into *orichalcum* by means of *cadmia*, a species of earth which they threw upon the copper, and which it absorbed. It has indeed been contended that the *cadmia* of Pliny was native arsenic; an opinion which scarcely merits confutation, but which must appear extremely groundless, when we reflect that it is impossible to make either brass or copper from arsenic, and that Pliny expressly calls the substance from which brass was made a *stone*. The testimony of Ambrose bishop of Milan in the fourth century, and of Primasius bishop of Adrumetum, in Africa, in the sixth, and of Isidorus bishop of Seville in the seventh, all seem to confirm Pliny's account. We may therefore safely conclude, that the Romans knew the method of making brass by mixing *cadmia* or *calamine* with copper. Yet it is probable they were not the inventors of this art, but borrowed it from some other country. It appears from a variety of testimonies that brass was made in Asia, in a manner similar to that employed at Rome; and a variety of places are mentioned where it was commonly made. It is supposed by some that in India, as well as in other parts of Asia, it was made in the remotest ages.

With respect to *orichalcum*, it is generally supposed that there were two sorts of this metal, one factitious, and the other natural. The factitious, whether we consider its qualities or its composition, appears to have been the same with our brass. As to the natural *orichalcum*, there is no impossibility in supposing that copper ore may have been so intimately blended with an ore of zinc, or of some other metallic substance, that the compound, when smelted, might yield a mixed metal of a paler hue than copper, and resembling the colour of gold or of silver.

We know of no country in which *orichalcum* is found at present; nor was it anywhere found in the age of Pliny, who does not seem to have known the country where it had ever been obtained. He admits, indeed, that it had been formerly dug out of the earth; but it is remarkable, that in the very passage where he mentions by name the countries most celebrated for the production of different kinds of copper, he only says in general, concerning *orichalcum*, that it had been found in other countries, but without specifying any particular country. Plato acknowledges that *orichalcum* was a thing only talked of even in his time; it was then nowhere to be met with, although in the island of Atlantis it had been formerly extracted from the mine. The Greeks were in possession of a metallic substance called *orichalcum* before the foundation of Rome. It is mentioned by Homer and by Hesiod, and by both of these poets in such a manner as shows that it was then held in great esteem. Other ancient writers have expressed themselves in similar terms of commendation; and it is principally from the circumstance of the high reputed value of *orichalcum* that authors have been induced to suppose that the ancient metal of this name was a natural substance, very different from the factitious one in use at Rome, and probably in Asia, and which, it has been shown, was in no respect different from our brass.

But this conclusion cannot be validly deduced from their encomiums upon *orichalcum;* for, at whatever time the method of making it was first discovered, its novelty and scarcity, joined to its utility, would enhance its value; at least there can be no absurdity in supposing, that when first introduced it was greatly prized, even though it be granted that it possessed no other properties than such as appertain to brass.

With respect to the etymology of the word there exists great diversity of opinions. Those who write it *aurichalcum* think it is composed of the Latin word *aurum*, gold, and the Greek χαλκος, *brass* or *copper*. But the most general opinion is that it is composed of ὄρος, *a mountain*, and χαλκος, *brass*, alluding perhaps to its being found in mountains or mountainous countries.

ORIENT, L', an arrondissement of the department of Morbihan, in France, which extends over 665 square miles. It comprehends eleven cantons, divided into fifty-two communes, and in 1836 it contained 133,307 inhabitants. The capital is the city of the same name. It is a fortified seaport, and a royal naval arsensal, standing at the mouth of the river Scorf, where it enters the bay of Port Louis. There are all those establishments for the building and equipping of ships of war. It is a well-built place, with long straight streets, and very fine quays. It has three churches, a naval hospital, 2000 houses, and 18,975 inhabitants. It is considerable also as a commercial port, is a dépôt for East India commodities, and has a great trade to the West Indies and the north of Europe. Long. 3. 30. W. Lat. 47. 48. 11. N.

Origen.

ORIGEN, a celebrated ecclesiastical writer, and one of the greatest geniuses, as well as most learned men, of the church, during the third century, was born at Alexandria in the year 185. He was surnamed *Adamantius*, either from his indefatigable application to study, or from the firmness he discovered amidst the torments which he suffered for the faith. Leonidas, his father, trained him with great care, and caused him, from his infancy, to apply to the study of the Scriptures, in which he made surprising progress. The son's inclination and turn of mind suited exactly with the father's design; for he pursued his studies with extraordinary zeal and ardour; and, being endowed with a quick apprehension and a strong imagination, he did not content himself with that sense which at first presented itself, but endeavoured to discover mysterious and allegorical explications of the sacred books. He would sometimes even puzzle his father, by soliciting the latter for recondite meanings; which obliged the good man to reprehend him a little, and withal to advise him not to attempt to penetrate too far in the study of the Scriptures, but to content himself with their clear, obvious, and natural sense. Hence it appears how early he was seized with that *furor allegoricus*, as a learned modern calls it, that rage of expounding the Scriptures allegorically, which afterwards became a distemper, and carried him to excesses which can never be excused. In philosophy he had the celebrated Ammonius as his teacher, and St Clement of Alexandria for his master in divinity. At eighteen years of age he succeeded the latter in the office of catechist; an important employment, which consisted in teaching divinity, and in expounding the Scriptures. Leonidas his father had suffered martyrdom the year before, during the persecution of Severus, in 202; and Origen had shown such eagerness to follow his father to martyrdom, that his mother was obliged to hide his clothes to prevent him going abroad. Origen had a great concourse of auditors who attended his school, some of whom were of the faithful, and the others Pagans. He confirmed and strengthened the former in their faith, and converted most of the latter; and there were such a number of martyrs amongst his disciples, that it might be said that he kept a school of martyrdom rather than one of divinity. He taught the doctrines of Christianity to the women and girls, as well as to the men; and taking in a too literal sense what Christ says of becoming voluntary eunuchs, castrated himself, to prevent his deserving or suffering scandal. He took a voyage to Rome in 211, in the beginning of the reign of Caracalla, under the pontificate of Zepherinus. On his return he published many works, whereby he acquired an extraordinary reputation, which drew to him a great number of auditors. But Demetrius, bishop of Alexandria, conceiving a jealousy of him, endeavoured upon various pretences to injure him. At length Origen went to Antioch, whither the Empress Mammæa had sent for him to hear him discourse on the Christian religion. He did not however stay long there, but returned to Alexandria, where he continued to teach till the year 228, when he left that city and travelled into Achaia. He then went into Palestine, and was ordained by the bishops of that province at forty-two years of age. But the circumstance of his being ordained by foreign bishops, without the permission of Demetrius, renewed that prelate's resentment against him; upon which Origen hastily returned to Alexandria, to endeavour to mollify him. Demetrius, however, drove him thence in the year 231, and caused him to be excommunicated, and even deposed, in a council which was held in Egypt. Origen then retired to Cæsarea in Palestine, where he raised a celebrated school, and had St Gregory Thaumaturgus, and a great number of other persons who were illustrious for their virtue and learning, as his disciples. He afterwards travelled to Athens, and, at the desire of Firmilianus, staid some time at Cæsarea in Cappadocia; whence he was invited into Arabia, to convince and bring back to the truth Beryllus bishop of Bostra, who maintained that the Word had no existence before his incarnation. Origen had the happiness to make him sensible of his mistake; and some years afterwards he was sent into Arabia by an assembly of bishops, to dispute against certain persons who maintained that the souls of the dead remained in a state of insensibility till the general resurrection. At length the seventh persecution of the Christians began in the reign of Decius, and none was treated with greater severity than Origen. He supported with incredible constancy the dreadful torments which the persecutors of the Christians invented against them; torments which were the more insupportable, as they were made to continue for a long time, and as the persecutors took the greatest care to prevent his expiring in the midst of his tortures. But in the most excruciating agony he discovered an heroic courage, and suffered nothing to escape him which was unworthy a disciple of Jesus Christ. Origen died at Tyre in the year 254, aged sixty-nine. He was the author of a great number of excellent works. The principal of those which have descended to us are, 1. A Treatise against Celsus, of which a good edition in Greek and Latin, with notes, has been published by Spencer; 2. A number of Homilies, with Commentaries on the Holy Scriptures; 3. Philocalia, and several other treatises; 4. Fragments of his Hexapla, collected by Montfaucon, in two volumes folio. Of all Origen's works, the loss of the Hexapla is most to be regretted. This work was thus named from its containing six columns, in the first of which was the Hebrew text of the Bible; in the second, the same text in Greek characters; in the third, the Greek version of the Septuagint; in the fourth, that of Aquila; in the fifth, that of Symmachus; and in the sixth, Theodosian's Greek version. This admirable work first suggested the idea of our Polyglot Bibles. Of the book of Principles we have only an incorrect Latin version. The most complete edition of the works of Origen is that of Father Delarue, a Benedictine, in Greek and Latin. Montfaucon likewise published, in two volumes folio, some remains and fragments of his Hexapla. He ought not to be confounded with another Origen, a Platonic philosopher, and the disciple and friend of Porphyry, who studied philosophy under Ammonius. This Origen was perhaps the founder of the sect of Origenians.

ORIGENIANS (*Origeniani*) were ancient heretics. Epiphanus speaks of them as existing in his time; but their numbers, he says, were inconsiderable. He seems to fix their rise about the time of the great Origen; but he does not say that they derived their name from that distinguished father of the church. On the contrary, he distinguishes them from the Origenists, whom he derives from *Origen Adamantius;* adding, that they first took their name from one Origen, by which he intimates that it was not the great Origen. St Augustin also asserts that their founder was a different person. Their doctrines were infamous. They rejected marriage; they used several apocryphal books, as the acts of St Andrew; and they endeavoured to excuse their open crimes, by saying that the Catholics committed the same in private.

ORIGENISTS, in *Ecclesiastical History*, a Christian sect in the fourth century, so called from their deriving their opinions from the writings of Origen. The Origenists maintained that the souls of men existed in a prior state; that they were holy intelligences, and had sinned in heaven before the body was created; that Christ is only the Son of God by adoption; that he has been successively united with all the angelical natures, and has been a cherub, a seraph, and all the celestial virtues one after another; that in future ages he will be crucified for the salvation of the devils, as he has already been for that of men; and that their punishment, and that of the damned, will continue only for a limited time.

ORIGINAL, a draught or design of any thing, which serves as a model to be imitated or copied.

Original Sin. See Theology.

ORILLON, in *Fortification*, a small rounding of earth, faced with a wall, and raised upon the shoulders of those bastions which have casemates, to cover the cannon in the retired flank, and prevent their being dismounted by the enemy.

ORINOCO, or Oronoko, a river of Colombia, in South America. Like all great rivers, its upper waters separate into several branches, and it does not appear that the main source has been ascertained with any degree of certainty. According to La Cruz d'Olmedilla, it issues from a small lake called Ypava, situated in north latitude 5° 5′, whence, by a bend of a spiral form, it enters the lake Parima; but although the existence of this sheet of water has been determined, doubts are entertained whether it may not owe its origin only to the temporary overflowings of the river. From this lake it is said to issue by two mouths; and after a very circuitous course of upwards of fifteen hundred miles, including its windings, it flows into the Atlantic Ocean, opposite to the island of Trinidad, by about fifty mouths, seven of which are navigable. The Grande Boca, or principal mouth, which is six leagues wide, is south-east of Trinidad, in latitude 8° 30′ north, and longitude 59° 50′ west. A soft mud bank, formed by the debris brought down by the river, and of course just an extension of the delta of the Orinoco, which will one day be clothed with vegetation, stretches a considerable way into the ocean on the left of the grand mouth, forming one line of the channel to the entrance of the river. The other side of this channel consists of hard ground, covered with shells and shingles, and on which the water deepens and shoals continually. At its estuary it presents the appearance of a boundless lake, and for a great extent its fresh waters penetrate into the bosom of the ocean, almost uncontaminated by saline matter. "Its green-coloured stream," says Humboldt, "and its waves dashing over rocks in milk-white foam, are strongly contrasted with the deep blue of the sea, which is separated from them by a strongly marked line." Such is the force of the stream formed by the Orinoco between the main land and the island of Trinidad, that vessels overcome it with great difficulty, even when favoured by a fresh breeze from the west. This solitary and dreadful place, perpetually tormented as if by a whirlpool, is called the Melancholy Gulf, the entrance to which is formed by the Dragon's Mouth. There, in the midst of furious waves, says the great traveller just quoted, enormous rocks raise their isolated heads, the remains of that ancient dike which formerly joined the island of Trinidad to the coast of Paria. It was the aspect of these places which first convinced Columbus of the existence of the continent of America. The unrivalled navigator reasoned admirably when he concluded that such an immense body of water must have accumulated during a very lengthened course, and that the country through which it flowed must be a continent, and not an island. He, however, supposed it to be a continuation of the coast of Asia; and, from the ethereal clearness of the sky, the refreshing mildness of the evening air, and the aromatic odours which came wafted by breezes from the land, the Orinoco appeared to him to be one of the four streams which issued from the terrestrial paradise to fructify and divide the earth, and he believed that he was about to set foot in the garden of Eden.
